Turbo Pascal is designed to meet the needs of all types of users of IBM PS/2s, PCs, and compatibles. It is a structured, high-level language you can use to write programs for any type or size of application.

Turbo Pascal 6.0 builds on what is already the world’s standard Pascal compiler. Fully compatible with code written using earlier versions of Turbo Pascal, this new version also includes

- a brand new, state-of-the-art integrated development environment (IDE), with
  - multiple overlapping windows
  - mouse support, menus, dialogs
  - multi-file editor that can edit files up to 1 Mb
  - enhanced debugging facilities
  - complete save and restore of desktop
- an object-oriented application framework, Turbo Vision, for use in your applications (it gives you the same tools we used to write the IDE)
- a full-featured inline assembler
- private fields and methods in object declarations
- extended syntax directive ($X) that lets you treat functions like procedures (and ignore function results)
- 286 code generation ($G directive)
- address references in typed constants
- far and near procedure directives
- link in initialized data ($L) from object files
- new heap manager is faster and reduces fragmentation (FreeMin and FreeList have been replaced; refer to Chapter 16 in the Programmer's Guide for more information)

For more about compiler directives, refer to Chapter 21 in the Programmer's Guide.
enhanced hypertext online help facilities, with complete cut-and-paste example code for every library procedure and function

The Turbo Pascal manuals

The four manuals in the Turbo Pascal documentation set serve four different purposes. Briefly, here’s what each contains:

The User's Guide (this book) contains information on how to install, learn and use Turbo Pascal's integrated environment and command-line compilers. It also includes information on the basics of programming in Turbo Pascal, as well as more advanced topics like debugging, object-oriented programming, and management of larger projects.

The Programmer's Guide is a reference guide to technical aspects of Turbo Pascal, describing in detail the definition of the language, the contents of the standard libraries, how they are implemented in Turbo Pascal, and use of Turbo Pascal with assembly language. This volume also contains explanations of all compiler directives and error messages used by Turbo Pascal.

The Library Reference contains an alphabetical reference to all the standard procedures and functions supported by the Turbo Pascal run-time library.

The Turbo Vision Guide tells you all about the Turbo Vision object-oriented application framework for building windowing applications. This volume contains step-by-step tutorials on how to put together a Turbo Vision application, reference material on all the tools provided in the library, and an alphabetical reference for all the objects, procedures, functions, and types in Turbo Vision.

Installing Turbo Pascal

Turbo Pascal comes with an automated installation program called INSTALL. You should use INSTALL to load Turbo Pascal onto your system, as it will ensure that you get all the files you need into the places that you need them. INSTALL will automatically create directories and copy files from the distribution disks to your hard disk. INSTALL's operation is
If you don’t already know how to use DOS commands, refer to your DOS reference manual before setting up Turbo Pascal on your system.

self-explanatory. If you have installed earlier versions of Turbo Pascal or Turbo C++, you are already familiar with the process. We assume you are already familiar with DOS commands. For example, you’ll need the DISKCOPY command to make backup copies of your distribution disks. Make a complete working copy of the distribution disks when you receive them, then store the original disks away in a safe place.

If you are not familiar with Borland’s No-Nonsense License Statement, read the agreement included with your Turbo Pascal package. Be sure to mail us your filled-in product registration card; this guarantees that you’ll be among the first to hear about the hottest new upgrades and versions of Turbo Pascal.

If you intend to use Turbo Pascal on a floppy-disk-only system, please read the information in the README file about floppy disk installation first.

To install Turbo Pascal on a hard disk:

■ Insert the installation diskette into drive A.
■ Type the command

A: INSTALL
and press Enter.
■ Press Enter at the installation screen.
■ Follow the prompts.

When it is finished, INSTALL reminds you to read the README file, which contains last-minute details about this release. INSTALL also tells you how to configure your CONFIG.SYS and AUTOEXEC.BAT files to use Turbo Pascal.

Also, once you’ve installed Turbo Pascal, you’ll have a chance to try out TPTOUR. TPTOUR is a guided tour of some of the highlights of the new Turbo Pascal integrated environment. TPTOUR is installed by default in your main Turbo Pascal directory.

After installing Turbo Pascal and trying out TPTOUR, you may be anxious to get up and running with the new IDE. If so, just get to the directory that holds your newly-installed Turbo Pascal programs and type TURBO, then press Enter. Otherwise, just keep reading the rest of this introduction for more important startup information.
Customizing Turbo Pascal

The new integrated environment allows you to do all customization (colors, options, preferences) without exiting the program to use external utilities. You can also specify some options at the command line when you start the integrated environment (see Chapter 7).

If you want the IDE to save and restore your desktop between sessions, go to the Preferences dialog box (Options | Environment) and turn Auto Save on for both Environment and Desktop.

Laptop systems

If you have a laptop computer with an LCD or plasma display, in addition to carrying out the procedures given in the previous sections, you need to set your screen parameters before using Turbo Pascal. The Turbo Pascal integrated environment version works best if you type `MODE BW80` at the DOS prompt before running Turbo Pascal.

Although you could create a batch file to take care of this, you can also easily customize Turbo Pascal for a black-and-white screen with the Startup Options dialog box in the IDE (Options | Environment | Startup).

The README file

The README file contains last-minute information that may not be in these manuals. It also lists every file on the distribution disks, with a brief description of what each one contains.

Here's how to access the README file:

1. If you haven’t installed Turbo Pascal yet, insert your Turbo Pascal installation disk into drive A.
2. Type `A:` and press Enter.
3. Type `README` and press Enter. Once you are in README, use the ↑ and ↓ keys to scroll through the file.
4. Press Esc to exit.
If you've already installed Turbo Pascal, you can open README in an edit window by following these steps:

1. Start Turbo Pascal from the directory in which you installed it by typing `TURBO` and pressing `Enter`.
2. Press `F3`. Type in `README` and press `Enter`. Turbo Pascal will open the README file in an edit window.
3. When you're done with the README file, press `Alt-F3` to close the editor window or `Alt-X` to leave the IDE.

**Typefaces used in these books**

All typefaces used in this manual were produced by Borland's Sprint: The Professional Word Processor, on a PostScript laser printer. Their uses are as follows:

**Monospace type**

This typeface represents text as it appears on-screen or in a program. It is also used for anything you must type (such as `TURBO` to start up Turbo Pascal).

Square brackets in text or DOS command lines enclose optional items that depend on your system. *Text of this sort should not be typed verbatim.*

**Boldface**

This typeface is used in text for Turbo Pascal reserved words, for compiler directives `{$I-}` and for command-line options `/A`.

**Italics**

Italics indicate identifiers that appear in text. They can represent terms that you can use as is, or that you can think up new names for (your choice, usually). They are also used to emphasize certain words, such as new terms.

**Keycaps**

This typeface indicates a key on your keyboard. For example, "Press Esc to exit a menu."

This icon indicates keyboard actions.

This icon indicates mouse actions.

How to contact Borland

The best way to contact Borland is to log on to Borland's Forum on CompuServe: Type GO BOR from the main CompuServe menu and choose "Borland Programming Forum A (Turbo Pascal)" from the Borland main menu. Leave your questions or comments there for the support staff to process.

If you prefer, write a letter with your comments and send it to

Borland International
Technical Support Department—Turbo Pascal
1800 Green Hills Road
P.O. Box 660001
Scotts Valley, CA 95067-0001, USA

You can also telephone our Technical Support department between 6 am and 5 pm Pacific time at (408) 438-5300. Please have the following information handy before you call:

1. Product name and serial number on your original distribution disk. Please have your serial number ready, or we won't be able to process your call.
2. Product version number. The version number for Turbo Pascal is displayed when you first load the program and before you press any keys.
3. Computer brand, model, and the brands and model numbers of any additional hardware.
4. Operating system and version number. (The version number can be determined by typing VER at the DOS prompt.)
5. Contents of your AUTOEXEC.BAT file.

See the README file included with your distribution disks for details on how to report a bug.
Learning the new IDE

Turbo Pascal is more than just a fast Pascal compiler; it is an efficient Pascal compiler with an easy-to-learn and easy-to-use integrated development environment (for short, we call it the IDE). With Turbo Pascal, you don’t need to use a separate editor, compiler, linker, and debugger in order to create, debug, and run your Pascal programs. All these features are built into Turbo Pascal, and they are all accessible from the IDE.

You can begin building your first Turbo Pascal program using the compiler built into the IDE. By the end of this chapter, you’ll have learned your way around the development environment, written and saved three small programs, and learned some basic programming skills.

Online context-sensitive help is only a keystroke (or a mouse click) away. You can get help at any point (except when your program has control) by pressing the shortcut F1. The Help menu (Alt-H) provides you with a table of contents to the help system, a detailed index, searching capabilities (Ctrl-F1), the ability to go back to other screens (Alt-F1), and help on Help (F1 when you’re already in help). Any help screen can contain one or more keywords (highlighted items) on which you can get more information.

If you want more detail about the IDE, look at Chapter 7, “The IDE reference.”
The components

We often abbreviate menu items. For example, to choose add a watch (Debug | Watch | Add Watch); we'll tell you to choose D | W | Add Watch.

There are three visible components to the IDE: the menu bar at the top, the desktop, and the status line at the bottom. Many menu items also offer dialog boxes. Before we detail each menu item in the IDE, we'll describe these more generic components.

The menu bar and menus

The menu bar is your primary access to all the menu commands. The only time the menu bar is not visible is when you're viewing your program's output. You'll see a highlighted menu title when the menu bar is active; this is the currently selected menu.

If a menu command is followed by an ellipsis mark (...), choosing the command displays a dialog box. If the command is followed by an arrow (•), the command leads to another menu (a pop-up menu). A command without either an ellipsis mark or an arrow indicates that the action occurs once you choose it.

Here is how you choose menu commands using just the keyboard:

1. Press F10. This makes the menu bar active.
2. Use the arrow keys to select the menu you want to display. Then press Enter.
   As a shortcut for this step, you can just press the highlighted letter of the menu title. For example, from the menu bar, press E to quickly display the Edit menu. From anywhere, press Alt and the highlighted letter to display the menu you want.
3. Use the arrow keys again to select the command you want. Then press Enter.
   Again, as a shortcut, you can just press the highlighted letter of a command to choose it once the menu is displayed.
   At this point, Turbo Pascal either carries out the command, displays a dialog box, or displays another menu.

You can also use a mouse to choose commands. The process is this:
1. Click the desired menu title to display the menu.
2. Click the desired command.

You can also drag straight from the menu title down to the menu command. Release the mouse button on the command you want. (If you change your mind, just drag off the menu; no command will be chosen.)

Note that some menu commands are unavailable when it would make no sense to choose them. You can still select (highlight) an unavailable command in order to get online help about it.

Turbo Pascal offers a number of quick ways to choose menu commands. For example, mouse users can combine the two-step process into one by dragging from the menu title down to the menu commands and releasing the mouse button when the command you want is selected.

From the keyboard, you can use a number of shortcuts (or hot keys) to access the menu bar and choose commands. You can get to, or activate, main menu items by pressing Alt and the highlighted letter. Once you’re in a menu, you can press an item’s highlighted letter or the shortcut next to it. You can also click on shortcuts on the status line.

The following tables list the most-used Turbo Pascal hot keys:

Turbo Pascal windows

Most of what you see and do in the IDE happens in a window. A window is a screen area that you can move, resize, zoom, tile, overlap, close, and open.

You can have any number of windows open in Turbo Pascal (memory and heap space allowing), but only one window can be active at any time. The active window is the one that you’re currently working in. Any command you choose or text you type generally applies only to the active window. There are several types of windows, but most have these things in common:

- a title bar
- a close box
- scroll bars
- a resize corner

Chapter 1, Learning the new IDE 11
- a zoom box
- a window number

Turbo Pascal makes it easy to spot the active window by placing a double-lined border around it. The active window always has a close box, a zoom box, scroll bars, and a resize corner. If your windows are overlapping, the active window is always the one on top of all the others (the frontmost one).

The Edit window also displays the current line and column numbers in the lower left corner. If you've modified your file, an asterisk (*) will appear to the left of the column and line numbers.

This is what a typical window looks like:

![Figure 1.1: A typical window]

The close box of a window is the box in the upper left corner. You click this box to quickly close the window. (Or choose Window | Close or press Alt-F3.) The Help window is considered temporary; you can close it by pressing Esc.
The **title bar**, the topmost horizontal bar of a window, contains the name of the window and the window number. Double-clicking the title bar zooms the window (and vice versa). You can also drag the title bar to move the window around.

Each of the windows you open in Turbo Pascal have a **window number** in the upper right border. `Alt-0` (zero) gives you a list of all windows you have open. You can make a window active (bringing it to the top of the heap) by pressing `Alt` in combination with the window number. For example, if the Help window is #5 but has gotten buried under the other windows, `Alt-5` brings it to the front.

The **zoom box** of a window appears in the upper right corner. If the icon in that corner is an up arrow (↑), you can click the arrow to enlarge the window to the largest size possible. If the icon is a doubleheaded arrow (↕), the window is already at its maximum size. In that case, clicking it returns the window to its previous size. To zoom a window from the keyboard, choose **Window > Zoom**, or press `F5`.

**Scroll bars** are horizontal or vertical bars that look like this:

```
<table>
<thead>
<tr>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
</tr>
<tr>
<td></td>
</tr>
<tr>
<td></td>
</tr>
<tr>
<td></td>
</tr>
<tr>
<td></td>
</tr>
<tr>
<td>---------------------------------</td>
</tr>
</tbody>
</table>
```

You use these bars with a mouse to scroll the contents of the window. Click the arrow at either end to scroll one line at a time. (Keep the mouse button pressed to scroll continuously.) You can click the shaded area to either side of the scroll box to scroll a page at a time. Finally, you can drag the scroll box to any spot on the bar to quickly move to a spot in the window relative to the position of the scroll box.

The **resize box** is in the lower right corner of a window. You drag any corner to make the window larger or smaller. You can spot the resize corner by its single-line border instead of the double-line border used in the rest of the window. To resize using the keyboard, choose **Size/Move** from the **Window** menu, or press `Ctrl-F5`.

**Window management**

Table 1.7 gives you a quick rundown of how to handle windows in Turbo Pascal. Note that you don’t need a mouse to perform these actions—a keyboard works just fine.

</tbody>

The status line

The status line appears at the bottom of the screen; it

- reminds you of basic keystrokes and shortcuts applicable at that moment in the active window.
- lets you click the shortcuts to carry out the action instead of choosing the command from the menu or pressing the shortcut keystroke.
- tells you what the program is doing. For example, it displays "Saving filename..." when an Edit file is being saved.
- offers one-line hints on any selected menu command and dialog box items.

The status line changes as you switch windows or activities. One of the most common status lines is the one you see when you're actually writing and editing programs in an Edit window. Here is what it looks like:

```
F1 Help  F2 Save  F3 Open  Alt-F9 Compile  F9 Make  F10 Menu
```

**Dialog boxes**

If a menu command has an ellipsis after it (...), the command opens a dialog box. A dialog box is a convenient way to view and set multiple options.

When you're making settings in dialog boxes, you work with five basic types of onscreen controls: radio buttons, check boxes, action buttons, input boxes, and list boxes. Here's a typical dialog box that illustrates some of these items:

![Typical Dialog Box](image)

This dialog box has three standard action buttons: OK, Cancel, and Help. If you choose OK, the choices in the dialog box are made in Turbo Pascal; if you choose Cancel, nothing changes and no action is made, but the dialog box is put away. Choose Help to open a Help window about this dialog box. Esc is always a keyboard shortcut for Cancel (even if no Cancel button appears).

If you're using a mouse, you can just click the button you want. When you're using the keyboard, you can press the highlighted letter of an item to activate it. For example, pressing K selects the OK button. Press Tab or Shift-Tab to move forward or back from one item to another in a dialog box. Each element highlights when it becomes active.
You can select another button with Tab; press Enter to choose that button.

Check boxes and radio buttons

You can have any number of check boxes checked at any time. When you select a check box, an X appears in it to show you it's on. An empty box indicates it's off. You check a check box (set it to on) by clicking it or its text, by pressing Tab until the check box (or its group) is highlighted and then pressing Spacebar, or by selecting the highlighted letter.

If selecting a check box in a group, use the arrow keys or highlighted letters to select the item you want, and then press Spacebar. On monochrome monitors, Turbo Pascal indicates the active check box or group of check boxes by placing a chevron symbol (») next to it. When you press Tab, the chevron moves to the next group of checkboxes or radio buttons.

Radio buttons are so called because they act just like the group of buttons on a car radio. There is always one—and only one—button pushed in at a time. Push one in, and the one that was in pops out.

Radio buttons differ from check boxes in that they present mutually exclusive choices. For this reason, radio buttons always come in groups, and exactly one (no more, no less) radio button can be on in any one group at any one time. To choose a radio button, click it or its text. From the keyboard, select the highlighted letter, or press Tab until the group is highlighted and then use the arrow keys to choose a particular radio button. Press Tab or Shift-Tab again to leave the group with the new radio button chosen.

Input boxes and lists

You're probably all familiar with input boxes; this is where you type in text. Most basic text-editing keys work in the text box (for example, arrow keys, Home, End, and insert/overwrite toggles by Ins). If you continue to type once you reach the end of the box, the contents automatically scroll. If there's more text than what shows in the box, arrowheads appear at the end (< and >). You can click the arrowheads to scroll or drag the text. If you need to enter control characters (such as ^L or ^M) in the input box, then prefix the character with a ^P. So, for example, entering ^P^L enters a ^L into the input box. This is useful for search strings.

If an input box has a down-arrow icon to its right, there is a history list associated with that input box. Press ↓ to view the...
history list and Enter to select an item from the list. The list will display any text you typed into the box the last few times you used it. If you want to reenter text that you already entered, press ↓ or click the ↓ icon. You can also edit an entry in the history list. Press Esc to exit from the history list without making a selection.

Here is what a history list for the Find text box might look like if you had used it seven times previously:

```
Text to find

date = record
  WriteIn('string[7]
  {}
  AbortCode
```

A final component of many dialog boxes is a list box. A list box lets you scroll through and select from variable-length lists without leaving a dialog box. If a blinking cursor appears in the list box and you know what you’re looking for, you can type the word (or the first few letters of the word) and Turbo Pascal will search for it.

You make a list box active by clicking it or by choosing the highlighted letter of the list title (or press Tab or the arrow keys until it’s highlighted). Once a list box is displayed, you can use the scroll box to move through the list or press ↑ or ↓ from the keyboard.

**Editing**

If you’re a longtime user of Borland products, the following summary of new editing features can help you identify the areas that are different from older products.

Turbo Pascal’s integrated editor now has

- mouse support
- support for large files (up to 1 Mb files; limited to 2 megabytes for all editors combined)
- Shift ↑ ↓ → ← for selecting text
- Edit windows that you can move, resize, or overlap
- multi-file capabilities let you open several files at once
Starting Turbo Pascal

If you have a low-density 5 1/4" floppy drive system, this procedure does not apply; read the README file for installation and operation details.

If you're using a floppy disk drive, put your Turbo Pascal system disk into Drive A and type the following command:

```
TURBO
```
Press Enter to run the program TURBO.EXE, which brings up the IDE.

If you’re using a hard disk, get into the Turbo Pascal subdirectory you created with INSTALL (the default is C: \ TP) and run TURBO.EXE by typing

```
TURBO
```
at the C: \ TP> prompt. Now you’re ready to write your first Turbo Pascal program.

Creating your first program

When you load Turbo Pascal (type TURBO and press Enter at the DOS prompt), what you’ll see is the main menu bar, a status line, an empty desktop, and a window with product version information (choosing the About command from the Help, or System, menu at any time will bring up this information). When you press any key, the version information disappears, but the windowed environment remains.

Press F10 to go the menu bar and then F3 (a shortcut for File | Open) to display the Open a File dialog box. You’re in the input box, so go ahead and type in MYFIRST (you don’t need the .PAS extension; it’s assumed) and then press Enter. Now you can start
typing in the following program, pressing Enter at the end of each line:

```
program MyFirst;
var
  A,B: Integer;
  Ratio: Real;
begin
  Write('Enter two numbers: '); Readln(A,B);
  Ratio := A / B;
  Writeln('The ratio is ',Ratio);
  Write('Press <Enter>...'); Readln;
end.
```

Use the Backspace key to make deletions, and use the arrow keys to move around in the edit window. If you’re unfamiliar with editing commands, Chapter 8 discusses all those available.

---

**Analyzing your first program**

While you can type in and run this program without ever knowing how it works, we’ve provided a brief explanation here. The first line you entered gives the program the name *MyFirst*. This is an optional statement, but it’s a good practice to include it.

The next three lines declare some *variables*, with the word *var* signaling the start of variable declarations. *A* and *B* are declared to be of type *Integer*; that is, they can contain whole numbers, such as 52, -421, 0, 32,283, and so on. *Ratio* is declared to be of type *Real*, which means it can hold fractional numbers such as 423.328 and -0.032, in addition to all integer values.

The rest of the program contains the *statements* to be executed. The word *begin* signals the start of the program. The statements are separated by semicolons and contain instructions to write to the screen (*Write* and *Writeln*), to read from the keyboard (*Readln*), and to perform calculations (*Ratio := A / B*). The *Readln* at the end of the program will cause execution to pause (until you press *Enter*) so you can inspect the program’s output. The program’s execution starts with the first instruction after *begin* and continues until *end* is encountered.
Saving your first program

After entering your first program, it's a good idea to save it to disk. To do this, choose the Save command from the File menu by pressing F10, then F to bring up the File menu and S to choose the Save command. An easier method would be to use the shortcut for File | Save, F2.

Compiling your first program

To compile your first program, go to the Compile option on the main menu. You can press F10 C, or Alt-C takes you right to it. Alt-F9 is the quickest shortcut, initiating compilation right away.

Turbo Pascal compiles your program, changing it from Pascal (which you can read) to 8086 machine code for the microprocessor (which your PC can execute). You don't see the 8086 machine code; it's stored in memory (or on disk).

Like English, Pascal has rules of grammar you must follow. However, unlike English, Pascal's structure isn't lenient enough to allow for slang or poor syntax—the compiler must always understand what you mean. In Pascal, when you don't use the appropriate words or symbols in a statement or when you organize them incorrectly, you will get a compile-time (syntax) error.

What compile-time errors are you likely to get? Probably the most common error novice Pascal programmers will get is

```
Unknown identifier
```

or

```
';' expected
```

Pascal requires that you declare all variables, data types, constants, and subroutines—in short, all identifiers—before using them. If you refer to an undeclared identifier or if you misspell it, you'll get an error. Other common errors are unmatched begin..end pairs, assignment of incompatible data types (such as assigning reals to integers), parameter count and type mismatches in procedure and function calls, and so on.

When you start compiling, a box appears in the middle of the screen, giving information about the compilation taking place. If no errors occurred during compilation, the message “Compilation
successful: press any key" flashes across the box. The box remains visible until you press a key. See how fast that went?

If an error occurs during compilation, Turbo Pascal stops, positions the cursor at the point of error in the editor, and displays an error message at the top of the editor, as it does with compile-time error messages. (The first key you press will clear the error message, and Ctrl-Q W will bring it back until you change files or recompile. Make the correction, save the updated file, and compile it again.)

---

Running your first program

After you’ve fixed any typing errors that might have occurred, go to the main menu and choose Run | Run (or press Ctrl-F9). You’re placed at the User screen, and the message

Enter two numbers:

appears on the screen. Type in any two integers (whole numbers), with a space between them, and press Enter. The following message will appear:

The ratio is

followed by the ratio of the first number to the second. On the next line the message “Press <Enter>...” will appear and the program will wait for you to press the Enter key. To review your program output, choose Window | User Screen (or press Alt-F5).

If an error occurs while your program is executing, you’ll get a message on the screen that looks like this:

Run-time error <errnum> at <segment>:<offset>

where <errnum> is the appropriate error number (see Appendix A in the Programmer’s Guide, “Error messages,” for information on compiler and run-time error messages), and <segment>:<offset> is the memory address where the error occurred. (If you need this number later, look for it in the Output window.) You’ll be positioned at the point of error in your program with a descriptive error message displayed on the editor status line. While the message is still on the editor status line, you can press F1 to get help with that particular error. Any other keystroke clears the error message. If you need to find the error location again, choose Search | Find Error.
When your program has finished executing, you’re returned to the place in your program where you started. You can now modify your program if you wish. If you choose the Run Run command before you make any changes to your program, Turbo Pascal immediately executes it again, without recompiling.

Once you’re back in the IDE after executing your program, you can view your program’s output by choosing the Run User Screen command (or by pressing Alt-F5). Choose it again to return to the Turbo Pascal environment.

Checking the files you’ve created

If you exit Turbo Pascal (choose Exit from the File menu), you can see a directory listing of the source (Pascal) file you’ve created. To exit, press D (for DOS Shell) in the File menu or, alternatively, press X (for Exit) and type the following command at the DOS prompt:

    DIR MYFIRST.*

You’ll get a listing that looks something like this:

    MYFIRST   PAS  217  8-10-88  11:07a

The file MYFIRST.PAS contains the Pascal program you just wrote. If you saved the program while you were typing, you’ll also see a backup file MYFIRST.BAK, which was created automatically by the editor.

You’ll only see the executable file if you’ve changed your default Destination setting in the Compile menu to Disk. You would then produce a file called MYFIRST.EXE, which would contain the machine code that Turbo Pascal generated from your program. You could then execute that program by typing MYFIRST followed by Enter at the DOS system prompt.

Stepping up: your second program

Now you’re going to write a second program that builds upon the first. If you exited from Turbo Pascal using the DOS Shell command from the File menu, you can return to the Turbo Pascal environment by typing EXIT at the DOS prompt. If you exited using Exit from the File menu, you would type

    TURBO MYFIRST.PAS
at the prompt in order to return to the IDE. This will place you directly into the editor. Now, modify your MYFIRST.PAS program to look like this:

```pascal
program MySecond;
var
    A, B: Integer;
    Ratio: Real;
begin
    repeat
        Write('Enter two numbers: ');
        Readln(A, B);
        Ratio := A / B;
        Writeln('The ratio is ', Ratio:8:2);
        Write('Press <Enter>...');
        Readln;
    until B = 0;
end.
```

You want to save this as a separate program, so go to the File menu, select Save As, and type in MYSECOND.PAS and press Enter.

Go ahead and compile and run your second program using Ctrl-F9. This is tells Turbo Pascal to run your updated program. And since you’ve made changes to the program, Turbo Pascal automatically compiles the program before running it.

A major change has been made to the program: The statements have been enclosed in the repeat..until loop. This causes all the statements between repeat and until to be executed until the expression following until is True. A test is made to see if B has a value of zero or not. If B has a value of zero, then the loop should exit.

Run your program, try out some values, then enter 1 0 and press Enter. Your program does exit, but not quite in the way you intended: It exits with a run-time error. You’re placed back in the editor, with the cursor in front of the line

```pascal
    Ratio := A / B;
```

and the message

```
Error 200: Division by zero
```

at the top of the edit window.
Debugging your program

If you’ve programmed before, you may recognize this error and how to fix it. But let’s take this opportunity to show you how to use the integrated debugger that’s built into Turbo Pascal 6.0.

Turbo Pascal’s integrated debugger allows you to step through your code one line at a time. At the same time, you can watch your variables to see how their values change.

To start the debugging session, choose the Run | Trace Into command (or press F7). If your program needs to be recompiled, Turbo Pascal will do so. The first statement (begin in this case) in the main body of your program is highlighted; from now on we’ll call this highlighted bar the run bar.

The first F7 you pressed initiated the debugging session. Now press F7 to begin executing the program. The debugger just executed the invisible startup code. The next executable line in this program is the Write statement on line 7.

Press F7 again. Your screen blinks momentarily, then shows your program with the run bar on the second statement (Readln).

What’s happening here is that Turbo Pascal switches to the User screen (where your program is executed and its output displayed), executes your first statement (a Write statement), then goes back to the editing screen.

Press F7 again. This time, the User screen comes up and stays there. That’s because a Readln statement is waiting for you to enter two numbers. Type two integer numbers, separated by a space; be sure the second number isn’t a zero. Now press Enter. You’re back at the Edit window, with the run bar on the assignment statement on line 9.

Press F7 and execute the assignment statement. Now the run bar is on the Writeln statement on line 10. Press F7 twice. Now you’re about to execute Readln on line 12. Press F7, inspect your program’s output, and then press Enter.

The run bar is on the until clause. Press F7 one more time, and you’re back at the top of the repeat loop.

Instead of racing through one program statement after another, the integrated debugger lets you step through your code one line at a time. This is a powerful tool, and we go into a more detailed
Using the Watch window

Let's take a look at the values of the variables you've declared. Press Alt-D to bring up the Debug. Choose the Add Watch command from the Watches menu (or press Ctrl-F7). Type A in the Watch Expression input box and press Enter. This puts A in the Watch window, along with its current value. Now use the Add Watch command to add B and Ratio to the Watch window. Finally, use it to add the expression A/B to the Watch window.

Choose Run | Trace Into (or press F7) to step through your program. This time, when you have to enter two numbers, enter 0 for the second number. When you press Enter and return to the IDE, look at the expression A/B in the Watch window (press Alt and the window # or Ctrl-WW). Instead of having a value after it, it has the phrase “Invalid floating-point operation”; that's because dividing by zero is undefined. Note, though, that having this expression in your Watch window doesn't cause the program to stop with an error. Instead, the error is reported to you and the debugger does not perform the division in the Watch window.

Now press F7 again, assigning A/B to Ratio. At this point, your program does halt, and the error message “Division by zero” appears at the top of the Edit window again.

Fixing your second program

Now you probably have a good idea of what's wrong with your program: If you enter a value of zero for the second number (B), the program halts with a run-time error.

How do you fix it? If B has a value of zero, don't divide B into A. Edit your program so that it looks like this:

```pascal
program MySecond;
var
  A,B: Integer;
  Ratio: Real;
begin
  repeat
    Write('Enter two numbers: '); Readln(A,B);
    if B = 0 then
      Writeln('The ratio is undefined')
    else
      Write('The ratio is: '); WriteLn(A/B)
  end;
end.
```

Discussion of debugging in Chapter 5. First, we'll give you a quick taste of debugging by tracking down that divide-by-zero error.
begin
  Ratio := A / B;
  Write('The ratio is ',Ratio:8:2);
end;
Write('Press <Enter>...');
Readln;
until B = 0;
end.

Now run your program (either by itself, or using the debugger). If you do use the debugger, note how the values in the Watch window change as you step through the program. When you’re ready to stop, enter 0 for B. The program will pause after printing the message “The ratio is undefined. Press <Enter>....”

Now you have an idea just how powerful the debugger is. You can step through your program line by line; you can display the value of your program’s variables and expressions, and you can watch the values change as your program runs.

Programming pizazz: your third program

For the last program, let’s get a little fancy and dabble in graphics. This program assumes that you have a graphics adapter for your system, and that you are currently set up to use that adapter. If you are in doubt, try the program and see what happens. If an error message appears, then you probably don’t have a graphics adapter (or you have one that’s not supported by our Graph unit). In any case, pressing Enter once should get you back to the IDE.

Open the file (F3) MYTHIRD.PAS and enter this program:

```pascal
program MyThird;
uses
  Graph;
const
  Start = 25;
  Finish = 175;
  Step = 2;
var
  GraphDriver: Integer;
  GraphMode: Integer;
  ErrorCode: Integer;
  X1,Y1,X2,Y2: Integer;
begin
  GraphDriver := Detect; { Stores graphics driver number }
  GraphMode := Integer; { Stores graphics mode for the driver }
  ErrorCode := Integer; { Reports an error condition }
  X1,Y1,X2,Y2: Integer;
end.
```
To run this program, you must be in the same directory as the BGI driver files (*.BGI).

```
InitGraph(GraphDriver, GraphMode, '');
ErrorCode := GraphResult;
if ErrorCode <> grOk then { Error? }
begin
  Writeln('Graphics error: ', GraphErrorMsg(ErrorCode));
  Writeln('You probably don’t have a graphics card!');
  Writeln('Program aborted...');
  Readln;
  Halt(1);
end;
Y1 := Start;
Y2 := Finish;
X1 := Start;
while X1 <= Finish do
begin
  X2 := (Start-Finish) - X1;
  Line(X1, Y1, X2, Y2);
  X1 := X1 + Step;
end;
X1 := Start;
X2 := Finish;
Y1 := Start;
while Y1 <= Finish do
begin
  Y2 := (Start-Finish) - Y1;
  Line(X1, Y1, X2, Y2);
  Y1 := Y1 + Step;
end;
OutText('Press <Enter> to quit:');
Readln;
CloseGraph;
end. { MyThird }
```

Save this program (F2) and then compile it (Alt-F9). If you have no errors during compilation, choose Run | Run (Ctrl-F9) to run it. This program produces a square with some wavy patterns along the edges. When execution is over, you’ll be returned to your program.

The `uses` clause says that the program uses a unit named `Graph`. A unit is a library, or collection, of subroutines (procedures and functions) and other declarations. In this case, the unit `Graph` contains the routines you want to use: `InitGraph`, `Line`, `CloseGraph`, and more.

The section labeled `const` defines three numeric constants—`Start`, `Finish`, and `Step`—that affect the size, location, and appearance of
the square. By changing their values, you can change how the square looks.

**Warning:** Don't set *Step* to anything less than 1; if you do, the program will get stuck in what is known as an *infinite loop* (a loop that circles endlessly). If you've compiled to disk and are running the .EXE from DOS, you won't be able to exit except by pressing *Ctrl-Alt Del* or by turning your PC off. If you're running from inside the IDE, you can interrupt the program by pressing *Ctrl-Break*.

The variables $X_1$, $Y_1$, $X_2$, and $Y_2$ hold the values of locations along opposite sides of the square. The square itself is drawn by drawing a straight line from $X_1,Y_1$ to $X_2,Y_2$. The coordinates are then changed, and the next line drawn. The coordinates always start out in opposite corners: The first line drawn goes from $(25,25)$ to $(175,175)$.

The program itself consists primarily of two loops. The first loop draws a line from $(25,25)$ to $(175,175)$. It then moves the $X$ (horizontal) coordinates by two, so that the next line goes from $(27,25)$ to $(173,175)$. This continues until the loop draws a line from $(175,25)$ to $(25,175)$.

The program then goes into its second loop, which pursues a similar course, changing the $Y$ (vertical) coordinates by two each time. The routine *Line* is from the *Graph* unit and draws a line between the endpoints given.

The final *Readln* statement causes the program to wait for you to press a key before it goes back into text mode and returns to the IDE.

You might want to step through this program line-by-line using the integrated debugger and then watch it swap back and forth between the program’s graphics mode and the IDE’s text mode.
Programming in Turbo Pascal

The Pascal language was designed by Niklaus Wirth in the early 1970s to teach programming. Because of that, it's particularly well-suited as a first programming language. And if you've already programmed in other languages, you'll find it easy to pick up Pascal.

To get you started on the road to Pascal programming, this chapter will teach you the basic elements of the Pascal language and show you how to use them in your programs. However, because we don't cover everything about Pascal programming here, you might want to pick up a copy of the *Turbo Pascal Disk Tutor* (Borland Osborne/McGraw Hill), a complete book-plus-disk tutorial about programming in Pascal and using Turbo Pascal.

Before you work through this chapter, you might want to read Chapter 7, “The IDE reference,” and Chapter 8, “The editor from A to Z,” to learn about the environment and text editor in Turbo Pascal. If you haven’t already installed Turbo Pascal as described in the introduction, you should do so now.

The elements of programming

Most programs are designed to solve a problem. They solve problems by manipulating information or data. As a programmer, you do the following:
• get the information into the program—input.
• have a place to keep it—data.
• give the right instructions to manipulate the data—operations.
• be able to get the data back out of the program to the user (you, usually)—output.

You can organize your instructions so that
• some are executed only when a specific condition (or set of conditions) is True—conditional execution.
• others are repeated a number of times—loops.
• others are broken off into chunks that can be executed at different locations in your program—subroutines.

These are the seven basic elements of programming: input, data, operations, output, conditional execution, loops, and subroutines. This list is not comprehensive, but it does describe those elements that programs (and programming languages) usually have in common.

Many programming languages, including Pascal, have additional features. And when you want to learn a new language quickly, you can find out how that language implements these seven elements, then build from there. Here's a brief description of each element:

Input
This means reading values in from the keyboard, from a disk, or from an I/O port.

Data
These are constants, variables, and structures that contain numbers (integer and real), text (characters and strings), or addresses (of variables and structures).

Operations
These assign one value to another, combine values (add, divide, and so forth), and compare values (equal, not equal, and so on).

Output
This means writing information to the screen, to a disk, or to an I/O port.

Conditional execution
This refers to executing a set of instructions if a specified condition is True (and skipping them or executing a different set
Data types

When you write a program, you’re working with information that generally falls into one of five basic types: integers, real numbers, characters and strings, Boolean, and pointers.

**Integers** are the whole numbers you learned to count with (1, 5, -21, and 752, for example).

**Real numbers** have fractional portions (3.14159) and exponents (2.579x10^24). These are also sometimes known as floating-point numbers.

**Characters** are any of the letters of the alphabet, symbols, and the numbers 0-9. They can be used individually (a, Z, !, 3) or combined into character strings (‘This is only a test.’).

**Boolean** expressions have one of two possible values: True or False. They are used in conditional expressions, which we’ll discuss later.

**Pointers** hold the address of some location in the computer’s memory, which in turn holds information.

**Integer data types**

Standard Pascal defines the data type integer as consisting of the values ranging from -MaxInt through 0 to MaxInt, where MaxInt is the largest possible integer value allowed by the compiler you’re using. Turbo Pascal supports type integer, defines MaxInt as equal to 32,767, and allows the value -32,768 as well. A variable of type Integer occupies 2 bytes.
Turbo Pascal also defines a long integer constant, \textit{MaxLongInt}, with a value of 2,147,483,647.

Turbo Pascal also supports four other integer data types, each of which has a different range of values. Table 2.1 shows all five integer types.

</tbody>
</table>

\textbf{A final note:} Turbo Pascal allows you to use hexadecimal (base 16) integer values. To specify a constant value as hexadecimal, place a dollar sign ($$) in front of it; for example, $$27 = 39$$ decimal.

Real data types

Standard Pascal defines the data type Real as representing floating-point values consisting of a significand (fractional portion) multiplied by an exponent (power of 10). The number of digits (known as \textit{significant digits}) in the significand and the range of values of the exponent are compiler-dependent. Turbo Pascal defines the type real as being 6 bytes in size, with 11 significant digits and an exponent range of $10^{-38}$ to $10^{38}$.

Turbo Pascal also supports the IEEE Standard 754 for binary floating-point arithmetic. This includes the data types Single, Double, Extended, and Comp. Single uses 4 bytes, with 7 significant digits and an exponent range of $10^{-45}$ to $10^{38}$; double uses 8 bytes, with 15 significant digits and an exponent range of $10^{-324}$ to $10^{308}$; and extended uses 10 bytes, with 19 significant digits and an exponent range of $10^{-4951}$ to $10^{4931}$.

If you have an 8087 math coprocessor and enable the numeric support compiler directive or environment option ([$\text{SN+}$]), Turbo Pascal generates the proper 8087 instructions to support these types and to perform all floating-point operations on the 8087.

If you don’t have an 8087 chip, but you still want to use the IEEE Standard types, you can ask Turbo Pascal to \textit{emulate} an 8087 chip, by enabling both the 8087 emulation and numeric processing compiler directives ([$\text{SE+}$] and [$\text{SN+}$], respectively). Turbo Pascal
then links in a special math library that performs floating-point functions just like an 8087 chip.

*comp only holds integer values.

Get into the Turbo Pascal editor and enter the following program:

```pascal
program DoRatio;
var
  A, B: Integer;
  Ratio: Real;
begin
  Write('Enter two numbers: ');
  Readln(A,B);
  Ratio := A div B;
  Writeln('The ratio is ',Ratio);
end.
```

Save this as DORATIO.PAS by selecting File|Save As from the main menu. Then press Alt-R to compile and run the program. Enter two values (such as 10 and 3) and note the result (3.000000). You probably expected an answer of 3.333333333, but instead you received a 3. That's because you used the div operator, which performs integer division. Go back and change the div statement to read as follows:

```pascal
Ratio := A / B;
```

Save the code (press F2), then compile and run. The result is now 3.333333333, as you expected. Using the division operator (/) gives you the most precise result—a real number.

You've learned how to store numbers in Pascal, now how about characters and strings? Pascal offers a predefined data type Char that is 1 byte in size and holds exactly one character. Character constants are represented by surrounding the character with single quotes (for example, 'A', 'e', '?', '2'). Note that '2' means the...
character 2, while 2 means the integer 2 (and 2.0 means the real number 2).

Here's a modification of DORATIO that allows you to repeat it several times (this also uses a repeat..until loop, which we'll discuss a little later):

```pascal
program DoRatio;
var
  A, B: Integer;
  Ratio: Real;
  Ans: Char;
begin
  repeat
    Write('Enter two numbers: '); Readln(A, B);
    Ratio := A / B;
    Writeln('The ratio is ', Ratio);
    Write('Do it again? (Y/N) '); Readln(Ans)
  until UpCase(Ans) = 'N'
end.
```

After calculating the ratio once, the program writes the message

Do it again? (Y/N)

and waits for you to type in a single character, followed by pressing Enter. If you type in a lowercase n or an uppercase N, the until condition is met and the loop ends; otherwise, the program goes back to the repeat statement and starts over again.

Note that n is not the same as N. This is because they have different ASCII code values. Characters are represented by the ASCII code: Each character has its own 8-bit number (characters take up 1 byte, remember).

Turbo Pascal gives you two additional ways of representing character constants: with a caret (^) or a number symbol (#). First, the characters with codes 0 through 31 are known as control characters (because historically they were used to control teletype operations). They are referred to by their abbreviations (CR for carriage return, LF for linefeed, ESC for escape, and so on) or by the word “Ctrl” followed by a corresponding letter (meaning the letter produced by adding 64 to the control code). For example, the control character with ASCII code 7 is known as BEL or Ctrl-G. Turbo Pascal lets you represent these characters using the caret (^), followed by the corresponding letter (or character). Thus, ^G
Boolean data type is a legal representation in your program of Ctrl-G, and you could write statements such as Writeln(^G), causing your computer to beep at you. This method, however, only works for the control characters.

You can also represent any character using the number symbol (#), followed by the character's ASCII code. Thus, #7 would be the same as ^G, #65 would be the same as 'A', and #233 would represent one of the special IBM PC graphics characters.

Individual characters are nice, but what about strings of characters? After all, that's how you will most often use them. Standard Pascal does not support a separate string data type, but Turbo Pascal does. Take a look at this program:

```
program Hello;
var
  Name: string[30];
begin
  Write('What is your name? ');
  Readln(Name);
  Writeln('Hello, ',Name)
end.
```

This declares the variable Name to be of type string, with space set aside to hold 30 characters. One more byte is set aside internally by Turbo Pascal to hold the current length of the string. That way, no matter how long or short the name is you enter at the prompt, that is exactly how much is printed out in the Writeln statement. Unless, of course, you enter a name more than 30 characters long, in which case only the first 30 characters are used, and the rest are ignored.

When you declare a string variable, you can specify how many characters (up to 255) it can hold. Or you can declare a variable (or parameter) to be of type String with no length mentioned, in which case the default size of 255 characters is assumed.

Turbo Pascal offers a number of predefined procedures and functions to use with strings; they can be found in Chapter 1 in the Library Reference.
importantly) an expression that resolves to one of those two values.

A **Boolean expression** is simply an expression that is either True or False. It is made up of relational expressions, Boolean operators, Boolean variables, and/or other Boolean expressions. For example, the following **while** statement contains a Boolean expression:

```pascal
while (Index <= Limit) and not Done do ...]
```

The Boolean expression consists of everything between the keywords **while** and **do**, and presumes that **Done** is a variable (or possibly a function) of type Boolean.

---

**Pointer data type**

All the data types we’ve discussed until now hold just that—data. A **pointer** holds a different type of information—an address. A pointer is a variable that contains the address in memory (RAM) where some data is stored, rather than the data itself. In other words, it points to the data, like an address book or an index.

A pointer is usually (but not necessarily) specific to some other data type. Consider the following declarations:

```pascal
type
    Buffer = string[255];
    BufPtr = ^Buffer;
var
    Buf1: Buffer;
    Buf2: BufPtr;
```

The data type **Buffer** is now just another name for **string[255]**, while the type **BufPtr** defines a pointer to a **Buffer**. The variable **Buf1** is of type **Buffer**; it takes up 256 bytes of memory. The variable **Buf2** is of type **BufPtr**; it contains a 32-bit address and takes up only 4 bytes of memory.

Where does **Buf2** point? Nowhere, currently. Before you can use **BufPtr**, you need to set aside (allocate) some memory and store its address in **Buf2**. You do that using the **New** procedure:

```pascal
New(Buf2);  
```

Since **Buf2** points to the type **Buffer**, this statement creates a 256-byte buffer somewhere in memory, then puts its address into **Buf2**.
How do you use the data pointed to by \textit{Buf2}? Via the indirection operator \(^\wedge\). For example, suppose you want to store a string in both \textit{Buf1} and the buffer pointed to by \textit{Buf2}. Here's what the statements would look like:

\begin{verbatim}
Buf1 := 'This string gets stored in Buf1.'
Buf2 := 'This string gets stored where Buf2 points.'
\end{verbatim}

Note the difference between \textit{Buf2} and \textit{Buf2}\(^\wedge\). \textit{Buf2} refers to a 4-byte pointer variable; \textit{Buf2}\(^\wedge\) refers to a 256-byte string variable whose address is stored in \textit{Buf2}.

How do you free up the memory pointed to by \textit{Buf2}? Using the \textit{Dispose} procedure. \textit{Dispose} makes the memory available for other uses. After you use \textit{Dispose} on a pointer, it's good practice to assign the (predefined) value \texttt{nil} to that pointer. That lets you know that the pointer no longer points to anything:

\begin{verbatim}
Dispose(Buf2);
Buf2 := nil;
\end{verbatim}

Note that you assign \texttt{nil} to \textit{Buf2}, not to \textit{Buf2}\(^\wedge\).

\section*{Identifiers}

Up until now, we've given names to variables without worrying about what restrictions there might be. Let's talk about those restrictions now.

The names you give to constants, data types, variables, and functions are known as \textit{identifiers}. Some of the identifiers used so far include

\begin{verbatim}
Integer, Real, String       Predefined data types
Hello,DoSum,DoRatio        Programs
Name, A, B, Sum, Ratio      User-defined variables
Write,Writeln,Readln       Predeclared procedures
\end{verbatim}

Turbo Pascal has a few rules about identifiers; here's a quick summary:

- All identifiers must start with a letter or underscore (\texttt{a}...\texttt{z}, \texttt{A}...\texttt{Z}, or \_). The rest of an identifier can consist of letters, underscores, and/or digits (0...9); no other characters are allowed.
Identifiers are *case-insensitive*, which means that lowercase letters (a...z) are considered the same as uppercase letters (A...Z). For example, the identifiers `indx`, `Indx`, and `INDX` are identical.

Identifiers can be of any length, but only the first 63 characters are significant.

Operators

Once you get your data into the program (and into your variables), you'll probably want to manipulate it somehow, using the operators available to you. There are eight operator types: assignment, arithmetic, bitwise, relational, logical, address, set, and string.

Most Pascal operators are *binary*, taking two operands; the rest are *unary*, taking only one operand. Binary operators use the usual algebraic form, for example, \( a + b \). A unary operator always precedes its operand, for example, \(-b\).

In more complex expressions, rules of precedence clarify the order in which operations are performed (see Table 2.3).

<table>

<td>Fourth (low)</td>

</tr>
</tbody>
</table>

Operations with equal precedence are normally performed from left to right, although the compiler may at times rearrange the operands to generate optimum code.

Sequences of operators of the same precedence are evaluated from left to right. Expressions within parentheses are evaluated first and independently of preceding or succeeding operators.

**Assignment operators**

The most basic operation is *assignment* (that is, assigning a value to a variable), as in `Ratio := A / B`. In Pascal, the assignment symbol is a colon followed by an equal sign (\( : = \)). In the example given, the value of \( A / B \) on the right of the assignment symbol is assigned to the variable `Ratio` on the left.
Arithmetic operators

Pascal supports the usual set of binary arithmetic operators—they work with type integer and real values:

- Multiplication (*)
- Integer division (div)
- Real division (/)
- Modulus (mod)
- Addition (+)
- Subtraction (-)

Also, Turbo Pascal supports both unary minus (a + (-b)), which performs a two's complement evaluation, and unary plus (a + (+b)), which does nothing at all but is there for completeness.

Bitwise operators

For bit-level operations, Pascal has the following operators:

- **shl** (shift left): Shifts the bits left the indicated number of bits, filling at the right with 0's.
- **shr** (shift right): Shifts the bits right the indicated number of bits, filling at the left with 0's.
- **and**: Performs a logical and on each corresponding pair of bits, returning 1 if both bits are 1, and 0 otherwise.
- **or**: Performs a logical or on each corresponding pair of bits, returning 0 if both bits are 0, and 1 otherwise.
- **xor**: Performs a logical, exclusive or on each corresponding pair of bits, returning 1 if the two bits are different from one another, and 0 otherwise.
- **not**: Performs a logical complement on each bit, changing each 0 to a 1, and vice versa.

These allow you to perform very low-level operations on integer values.

Relational operators

Relational operators allow you to compare two values, yielding a Boolean result of True or False. Here are the relational operators in Pascal:
>     greater than
>=     greater than or equal to
<     less than
<=     less than or equal to
=     equal to
<>     not equal to
in     is a member of

Why would you want to know if something were True or False? Enter the following program:

```
program TestGreater;
var
    A,B: Integer;
    Test: Boolean;
begin
    Write('Enter two numbers: ');
    Readln(A,B);
    Test := A > B;
    Writeln('A is greater than B', Test);
end.
```

This will print True if $A$ is greater than $B$ or False if $A$ is less than or equal to $B$.

Logical operators

There are four logical operators—and, xor, or, and not—which are similar to but not identical with the bitwise operators. These logical operators work with logical values (True and False), allowing you to combine relational expressions, Boolean variables, and Boolean expressions.

They differ from the corresponding bitwise operators in this manner:

- Logical operators always produce a result of either True or False (a Boolean value), while the bitwise operators do bit-by-bit operations on type integer values.
- You cannot combine Boolean and integer-type expressions with these operators; in other words, the expression Flag and Indx is illegal if Flag is of type Boolean, and Indx is of type integer (or vice versa).
- The logical operators and and or will short-circuit by default; xor and not will not. Suppose you have the expression exp1 and exp2. If exp1 is False, then the entire expression is False, so exp2 will never be evaluated. Likewise, given the expression exp1 or
exp2, exp2 will never be evaluated if exp1 is True. You can force full Boolean expression using the \texttt{$B+$} compiler directive or the Complete Boolean Eval option (Options | Compiler).

### Address operators

Pascal supports two special address operators: the \textit{address-of} operator (\texttt{@}) and the \textit{indirection} operator (\texttt{^}).

The \texttt{@} operator returns the address of a given variable; if \textit{Sum} is a variable of type integer, then \texttt{@Sum} is the address (memory location) of that variable. Likewise, if \textit{ChrPtr} is a pointer to type char, then \texttt{ChrPtr^} is the character to which \textit{ChrPtr} points.

### Set operators

Set operators perform according to the rules of set logic. The set operators and operations include

- \texttt{+} union
- \texttt{-} difference
- \texttt{*} intersection

### String operators

The only string operation is the \texttt{+} operator, which is used to concatenate two strings.

### Output

It may seem funny to talk about output before input, but a program that doesn’t output information isn’t of much use. That output usually takes the form of information written to the screen (words and pictures), to a storage device (floppy or hard disk), or to an I/O port (serial or printer ports).

### The WriteLn procedure

You’ve already used the most common output function in Pascal, the \texttt{WriteLn} routine. The purpose of \texttt{WriteLn} is to write information to the screen. Its format is both simple and flexible:

\begin{verbatim}
WriteLn(item, item, ...);
\end{verbatim}
Each *item* is something you want to print to the screen and can be a literal value, such as an integer or a real number (3, 42, -1732.3), a character (‘a’, ‘Z’), a string (‘Hello, world’), or a Boolean value (True). It can also be a named constant, a variable, a dereferenced pointer, or a function call, as long as it yields a value that is of type Integer, Real, Char, String, or Boolean. All the items are printed on one line, in the order given. The cursor is then moved to the start of the next line. If you wish to leave the cursor after the last item on the same line, then use the statement

```pascal
Write(item, item, ...);
```

When the items in a *Writeln* statement are printed, blanks are *not* automatically inserted; if you want spaces between items, you’ll have to put them there yourself, like this:

```pascal
WriteLn(item, ', item, ', ...);
```

For example, the following statements produce the indicated output:

```pascal
A := 1; B := 2; C := 3;
Name := 'Frank';
WriteLn(A,B,C);
WriteLn(A,' ',B,' ',C);
WriteLn('Hi' ,Name);
WriteLn(' Hi, ' ,Name,' .');
```

You can also use *field-width specifiers* to define a field width for a given item. The format for this is

```pascal
WriteLn(item:width,...);
```

where *width* is an integer expression (literal, constant, variable, function call, or combination thereof) specifying the total width of the field in which *item* is written. For example, consider the following code and resulting output:

```pascal
A := 10; B := 2; C := 100;
WriteLn(A,B,C);
WriteLn(A:2,B:2,C:2);  // 102100
WriteLn(A:3,B:3,C:3);  // 102100
WriteLn(A,B:2,C:4);    // 10 2 100
```

Note that the item is padded with leading blanks on the left to make it equal to the field width. The actual value is right-justified.

What if the field width is less than what is needed? In the second *Writeln* statement given earlier, C has a field width of 2 but has a
value of 100 and needs a width of 3. As you can see by the output, Pascal simply expands the width to the minimum size needed.

This method works for all allowable items: integers, reals, characters, strings, and Booleans. However, real numbers printed with the field-width specifier (or with none at all) come out in exponential form:

\[
X := 421.53;
\]

\[
\text{Writeln}(X);
\]  

\[
4.2153000000E+02
\]

\[
\text{Writeln}(X:8);
\]  

\[
4.2E+02
\]

Because of this, Pascal allows you to append a second field-width specifier: \textit{item:width:digits}. This second value forces the real number to be printed out in fixed-point format and tells how many digits to place after the decimal point:

\[
X := 421.53;
\]

\[
\text{Writeln}(X:6:2);
\]  

\[
421. 53
\]

\[
\text{Writeln}(X:8:2);
\]  

\[
421.53
\]

\[
\text{Writeln}(X:8:4);
\]  

\[
421.5300
\]

Input

Standard Pascal has two basic input functions that are used to read from data from the keyboard: \texttt{Read} and \texttt{Readln}. The general syntax is

\[
\texttt{Read(item,item,...)};
\]

or

\[
\texttt{Readln(item,item,...)};
\]

Each \texttt{item} is a variable of any integer, real, char, or string type. Numbers being input must be separated from other values by spaces or by pressing \textit{Enter}.

Conditional statements

There are times when you want to execute some portion of your program when a given condition is True or False, or when a particular value of a given expression is reached. Let's look at how to do this in Pascal.
The if statement

Look again at the if statement in the previous examples; note that it can take the following generic format:

```pascal
if expr
  then statement1
else statement2
```

`expr` is any Boolean expression (resolving to True or False), and `statement1` and `statement2` are legal Pascal statements. If `expr` is True, then `statement1` is executed; otherwise, `statement2` is executed.

We must explain two important points about if/then/else statements:

1. `else statement2` is optional; in other words, this is a valid if statement:

   ```pascal
   if expr
     then statement1
   ```

   In this case, `statement1` is executed only if `expr` is True. If `expr` is False, then `statement1` is skipped, and the program continues.

2. What if you want to execute more than one statement if a particular expression is True or False? You use a compound statement. A compound statement consists of the keyword `begin`, some number of statements separated by semicolons (;), and the keyword `end`.

The ratio example uses a single statement for the if clause

```pascal
if B = 0.0 then
  Writeln('Division by zero is not allowed.');
```

and a compound statement for the else clause

```pascal
else
  begin
    Ratio = A / B;
    Writeln('The ratio is ',Ratio)
  end;
```

You might also notice that the body of each program you’ve written is simply a compound statement followed by a period.
The case statement

else is an extension to standard Pascal.

This statement gives your program the power to choose from more than two alternatives without having to specify lots of if statements.

The case statement consists of an expression (the selector) and a list of statements, each preceded by a case label of the same type as the selector. It specifies that the one statement be executed whose case label is equal to the current value of the selector. If none of the case labels contain the value of the selector, then either no statement is executed or, optionally, the statements following the reserved word else are executed.

A case label consists of any number of constants or subranges, separated by commas and followed by a colon; for example,

```pascal
case BirdSight of
  'C', 'c': Curlews := Curlews + 1;
  'H', 'h': Herons := Herons + 1;
  'E', 'e': Egrets := Egrets + 1;
  'T', 't': Terns := Terns + 1;
end;  { case }
```

A subrange is written as two constants separated by the subrange delimiter '..'. The constant type must match the selector type. The statement that follows the case label is executed if the selector's value equals one of the constants or if it lies within one of the subranges.

Loops

Just as there are statements (or groups of statements) that you want to execute conditionally, there are other statements that you may want to execute repeatedly. This kind of construct is known as a loop.

There are three basic kinds of loops: the while loop, the repeat loop, and the for loop. We'll cover them in that order.
The while loop

You can use the **while** loop to test for something at the beginning of your loop. Enter the following program:

```pascal
program Hello;
var
  Count: Integer;
begin
  Count := 1;
  while Count <= 10 do
    begin
      Writeln('Hello and goodbye!');
      Inc(Count)
    end;
  Writeln('This is the end!')
end.
```

The first thing that happens when you run this program is that `Count` is set equal to 1, then you enter the while loop. This tests to see if `Count` is less than or equal to 10. `Count` is, so the loop’s body (begin..end) is executed. This prints the message Hello and goodbye! to the screen, then increments `Count` by 1. `Count` is again tested, and the loop’s body is executed once more. This continues as long as `Count` is less than or equal to 10 when it is tested. Once `Count` reaches 11, the loop stops, and the string This is the end! is printed on the screen.

The format of the while statement is

```pascal
while expr do statement
```

where `expr` is a Boolean expression, and `statement` is either a single or a compound statement.

The while loop evaluates `expr`. If it’s True, then `statement` is executed, and `expr` is evaluated again. If `expr` is False, the while loop is finished and the program continues.

The repeat..until loop

The second loop is the **repeat..until** loop, which we’ve seen in the program DORATIO.PAS:

```pascal
program DoRatio;
var
  A,B: Integer;
```
Ratio: Real;
Ans: Char;

begin
repeat
  Write('Enter two numbers: '); 
  Readln(A,B);
  Ratio := A / B;
  Writeln('The ratio is ',Ratio);
  Write('Do it again? (Y/N) ');
  Readln(Ans)
  until UpCase(Ans) = 'N'
end.

As described before, this program repeats until you answer \textit{Y} or \textit{N} to the question \textit{Do it again? (Y/N)}. In other words, everything between \texttt{repeat} and \texttt{until} is repeated until the expression following \texttt{until} is True.

Here's the generic format for the \texttt{repeat..until} loop:

\begin{verbatim}
repeat
  statement;
  statement;
  ...
  statement
until expr
\end{verbatim}

There are three major differences between the \texttt{while} loop and the \texttt{repeat} loop. First, the statements in the \texttt{repeat} loop always execute at least once, because the test on \textit{expr} is not made until after the \texttt{repeat} occurs. By contrast, the \texttt{while} loop will skip over its body if the expression is initially False.

Next, the \texttt{repeat} loop executes \textit{until} the expression is True, where the \texttt{while} loop executes \textit{while} the expression is True. This means that care must be taken in translating from one type of loop to the other. For example, here's the HELLO program rewritten using a \texttt{repeat} loop:

\begin{verbatim}
program Hello;
var
  Count: Integer;
begin
  Count := 1;
  repeat
    Writeln('Hello and goodbye!');
    Inc(Count)
  until Count > 10;
\end{verbatim}
Writeln('This is the end!')
end.

Note that the test is now \textit{Count > 10}, where for the \textbf{while} loop it was \textit{Count <= 10}.

Finally, the \textbf{repeat} loop can hold multiple statements without using a compound statement. Notice that you didn't have to use \texttt{begin..end} in the preceding program, but you did for the earlier version using a \textbf{while} loop.

Again, be careful to note that the \textbf{repeat} loop will always execute at least once. A \textbf{while} loop may or may not execute, depending on the value of the expression.

---

The for loop

The \textbf{for} loop is the one found in most major programming languages, including Pascal. However, the Pascal version is simultaneously limited and powerful.

Basically, the \textbf{for} loop executes a set of statements some fixed number of times while a variable (known as the \textit{index variable}) steps through a range of values. To see how this works, modify the earlier HELLO program to read as follows:

\begin{verbatim}
program Hello;
var
  Count: Integer;
begin
  for Count := 1 to 10 do
    Writeln('Hello and goodbye!');
  Writeln('This is the end!')
end.
\end{verbatim}

When you run this program, you can see that the loop works the same as the \textbf{while} and \textbf{repeat} loops already shown and, in fact, is precisely equivalent to the \textbf{while} loop. Here's the generic format of the \textbf{for} loop statement:

\begin{verbatim}
for index := expr1 to expr2 do statement
\end{verbatim}

\textit{Index} is a variable of some scalar type (any integer type, char, Boolean, any enumerated type), \texttt{expr1} and \texttt{expr2} are expressions of some type compatible with \textit{index}, and \textit{statement} is a single or compound statement. \textit{Index} is incremented by one after each time through the loop.
You can also decrement the index variable instead of incrementing it by replacing the keyword `to` with the keyword `downto`.

The `for` loop is equivalent to the following code:

```pascal
index := expr1;
while index <= expr2 do
begin
  statement;
  Inc(index)
end;
```

The main drawback of the `for` loop is that it only allows you to increment or decrement by one. Its main advantages are conciseness and the ability to use char and enumerated types in the range of values.

### Procedures and functions

You've learned how to execute code conditionally and iteratively. Now, what if you want to perform the same set of instructions on different sets of data or at different locations in your program? Well, you simply put those statements into a subroutine, which you can then call as needed.

In Pascal, there are two types of subroutines: *procedures* and *functions*. The main difference between the two is that a function returns a value and can be used in expressions, like this:

```pascal
X := Sin(A);
```

while a procedure is called to perform one or more tasks:

```pascal
Writeln('This is a test');
```

However, before you learn any more about procedures and functions, you need to understand Pascal program structure.

### Program structure

In Standard Pascal, programs adhere to a rigid format:

```pascal
program ProgName;
label
labels;
```
const
c   constant declarations;

type
data type definitions;

var
variable declarations;

procedures and functions;

begin
   main body of program
end.

You do not have to have all five declaration sections—label, const, type, var, and procedures and functions—in every program. But in standard Pascal, if they do appear, they must be in that order, and each section can appear only once. The declaration section is followed by any procedures and functions you might have, then finally the main body of the program, consisting of some number of statements.

Turbo Pascal gives you tremendous flexibility in your program structure. All it requires is that your program statement (if you have one) be first and that your main program body be last. Between those two, you can have as many declaration sections as you want, in any order you want, with procedures and functions freely mixed in. But identifiers must be defined before they are used, or else a compile-time error will occur.

Procedure and function structure

As mentioned earlier, procedures and functions—known collectively as subprograms—appear anywhere before the main body of the program. Procedures use this format:

procedure ProcName(parameters);
label
   labels;
const
   constant declarations;
type
   data type definitions;
var
   variable declarations;
procedures and functions;
begin
   main body of procedure;
end;
Functions look just like procedures except that a function declaration starts with a `function` header and ends with a data type for the return value of the function:

```pascal
function FuncName(parameters): data type;
```

As you can see, there are only two differences between this and regular program structure: Procedures or functions start with a `procedure` or `function` header instead of a `program` header, and they end with a semicolon instead of a period. A procedure or function can have its own constants, data types, and variables, and even its own procedures and functions. What’s more, all these items can only be used with the procedure or function in which they are declared.

Sample program

Here’s a version of the DORATIO program that uses a procedure to get the two values, then uses a function to calculate the ratio:

```pascal
program DoRatio;
var
  A, B: Integer;
  Ratio: Real;
procedure GetData(var X, Y: Integer);
begin
  Write('Enter two numbers: '); Readln(X, Y)
end;
function GetRatio(I, J: Integer): Real;
begin
  GetRatio := I/J
end;
begin
  GetData(A, B);
  Ratio := GetRatio(A, B);
  Writeln('The ratio is ', Ratio)
end.
```

This isn’t exactly an improvement on the original program, being both larger and slower, but it does illustrate how procedures and functions work.

When you compile and run this program, execution starts with the first statement in the main body of the program: `GetData(A, B)`. This type of statement is known as a `procedure call`. Your program handles this call by executing the statements in `GetData`, replacing...
X and Y (known as formal parameters) with A and B (known as actual parameters). The keyword var in front of X and Y in GetData's procedure statement says that the actual parameters must be variables and that the variable values can be changed and passed back to the caller. So you can't pass literals, constants, expressions, and so on to GetData. Once GetData is finished, execution returns to the main body of the program and continues with the statement following the call to GetData.

That next statement is a function call to GetRatio. Note that there are some key differences here. First, GetRatio returns a value, which must then be used somehow; in this case, it's assigned to Ratio. Second, a value is assigned to GetRatio in its main body; this is how a function determines what value to return. Third, there is no var keyword in front of the formal parameters I and J. This means that the actual parameters could be any two integer expressions, such as Ratio := GetRatio(A + B, 300); and that even if you change the values of the formal parameters in the function body, the new values will not be passed back to the caller. This, by the way, is not a distinction between procedures and functions; you can use both types of parameters with either type of subprogram.

Program comments

Sometimes you want to insert notes into your program to remind yourself (or inform someone else) of what certain variables mean, what certain functions or statements do, and so on. These notes are known as comments. Pascal, like most other programming languages, lets you put as many comments as you want into your program.

You can start a comment with the left curly brace (\{), which signals to the compiler to ignore everything until after it sees the right curly brace (\}).

Comments can even extend across multiple lines, like this:

\{
  This is a long
  comment, extending
  over several lines.
\}

Pascal also allows an alternative form of comment, beginning with a left parenthesis and an asterisk, (\*, and ending with an asterisk and a right parenthesis, *). This allows for a limited form
of comment nesting, because a comment beginning with (*
ignores all curly braces, and vice versa.
What is a unit?

Turbo Pascal units

In Chapter 1, you learned how to write standard Pascal programs. What about non-standard programming—more specifically, PC-style programming, with screen control, DOS calls, and graphics? To write such programs, you have to understand units or understand the PC hardware enough to do the work yourself. This chapter explains what a unit is, how you use it, what predefined units are available, how to go about writing your own units, and how to compile them.

What is a unit?

Turbo Pascal gives you access to a large number of predefined constants, data types, variables, procedures, and functions. Some are specific to Turbo Pascal; others are specific to the IBM PC (and compatibles) or to DOS. There are dozens of them, but you seldom use them all in a given program. Because of this, they are split into related groups called units. You can then use only the units your program needs.

A unit is a collection of constants, data types, variables, procedures, and functions. Each unit is almost like a separate Pascal program: It can have a main body that is called before your program starts and does whatever initialization is necessary. In short, a unit is a library of declarations you can pull into your program that allows your program to be split up and separately compiled.
All the declarations within a unit are usually related to one another. For example, the Crt unit contains all the declarations for screen-oriented routines on your PC.

Turbo Pascal provides eight standard units for your use. Six of them—System, Overlay, Graph, Dos, Crt, and Printer—provide support for your regular Turbo Pascal programs; these are all stored in TURBO.TPL. The other two—Turbo3 and Graph3—are designed to help maintain compatibility with programs and data files created under version 3.0 of Turbo Pascal. Some of these are explained more fully in Chapters 10 through 15 of the Programmer's Guide, but we'll look at each one here and explain its general function.

A unit's structure

A unit provides a set of capabilities through procedures and functions—with supporting constants, data types, and variables—but it hides how those capabilities are actually implemented by separating the unit into two sections: the interface and the implementation. When a program uses a unit, all the unit's declarations become available, as if they had been defined within the program itself.

A unit's structure is not unlike that of a program, but with some significant differences. Here's a unit, for example:

```pascal
unit <identifier>;
interface
uses <list of units>; { Optional }
{ public declarations }
implementation
uses <list of units>; { Optional }
{ private declarations }
{ implementation of procedures and functions }
begin
{ initialization code }
end.
```

The unit header starts with the reserved word unit, followed by the unit's name (an identifier), much the way a program begins. The next item in a unit is the keyword interface. This signals the start of the interface section of the unit—the section visible to any other units or programs that use this unit.
A unit can use other units by specifying them in a uses clause. The uses clause can appear in two places. First, it can appear immediately after the keyword interface. In this case, any constants or data types declared in the interfaces of those units can be used in any of the declarations in this unit's interface section.

Second, it can appear immediately after the keyword implementation. In this case, any declarations from those units can be used only within the implementation section. This also allows for circular unit references; you'll learn how to use these later in this chapter.

Interface section

The interface portion—the "public" part—of a unit starts at the reserved word interface, which appears after the unit header and ends when the reserved word implementation is encountered. The interface determines what is "visible" to any program (or other unit) using that unit; any program using the unit has access to these "visible" items.

In the unit interface, you can declare constants, data types, variables, procedures, and functions. As with a program, these can be arranged in any order, and sections can repeat themselves (for example, type ... var ... <procs> ... const ... type ... const ... var).

The procedures and functions visible to any program using the unit are declared here, but their actual bodies—implementations—are found in the implementation section. forward declarations are neither necessary nor allowed. The bodies of all the regular procedures and functions are held in the implementation section after all the procedure and function headers have been listed in the interface section.

A uses clause may appear in the implementation. If present, uses must immediately follow the keyword implementation.

Implementation section

The implementation section—the "private" part—starts at the reserved word implementation. Everything declared in the interface portion is visible in the implementation: constants, types, variables, procedures, and functions. Furthermore, the implementation can have additional declarations of its own,
although these are not visible to any programs using the unit. The program doesn’t know they exist and can’t reference or call them. However, these hidden items can be (and usually are) used by the “visible” procedures and functions—those routines whose headers appear in the interface section.

A uses clause may appear in the implementation. If present, uses must immediately follow the keyword implementation.

If any procedures have been declared external, one or more {$L filename} directive(s) should appear anywhere in the source file before the final end of the unit.

The normal procedures and functions declared in the interface—those that are not inline—must reappear in the implementation. The procedure/function header that appears in the implementation should either be identical to that which appears in the interface or should be in the short form. For the short form, type in the keyword (procedure or function), followed by the routine’s name (identifier). The routine will then contain all its local declarations (labels, constants, types, variables, and nested procedures and functions), followed by the main body of the routine itself. Say the following declarations appear in the interface of your unit:

```pascal
procedure ISwap(var V1, V2: Integer);
function IMax(V1, V2: Integer): Integer;
```

The implementation could look like this:

```pascal
procedure ISwap;
var
  Temp: Integer;
begin
  Temp := V1; V1 := V2; V2 := Temp;
end; { of proc ISwap }
function IMax(V1, V2: Integer): Integer;
begin
  if V1 > V2 then
    IMax := V1
  else IMax := V2;
end; { of func IMax }
```

Routines local to the implementation (that is, not declared in the interface section) must have their complete procedure/function header intact.
The entire implementation portion of the unit is normally bracketed within the reserved words `implementation` and `end`. However, if you put the reserved word `begin` before `end`, with statements between the two, the resulting compound statement—looking very much like the main body of a program—becomes the `initialization` section of the unit.

The initialization section is where you initialize any data structures (variables) that the unit uses or makes available (through the interface) to the program using it. You can use it to open files for the program to use later. For example, the standard unit `Printer` uses its initialization section to make all the calls to open (for output) the text file `Lst`, which you can then use in your program's `Write` and `Writeln` statements.

When a program using that unit is executed, the unit's initialization section is called before the program's main body is run. If the program uses more than one unit, each unit's initialization section is called (in the order specified in the program's `uses` statement) before the program's main body is executed.

How are units used?

The units your program uses have already been compiled and stored as machine code, not Pascal source code; they are not Include files. Even the interface section is stored in the special binary symbol table format that Turbo Pascal uses. Furthermore, certain standard units are stored in a special file (TURBO.TPL) and are automatically loaded into memory along with Turbo Pascal itself.

As a result, using a unit or several units adds very little time (typically less than a second) to the length of your program's compilation. If the units are being loaded in from a separate disk file, a few additional seconds may be required because of the time it takes to read from the disk.

As stated earlier, to use a specific unit or collection of units, you must place a `uses` clause at the start of your program, followed by a list of the unit names you want to use, separated by commas:
program MyProg;
uses thisUnit,thatUnit,theOtherUnit;

When the compiler sees this uses clause, it adds the interface information in each unit to the symbol table and links the machine code that is the implementation to the program itself.

The ordering of units in the uses clause is not important. If thisUnit uses thatUnit or vice versa, you can declare them in either order, and the compiler will determine which unit must be linked into MyProg first. In fact, if thisUnit uses thatUnit but MyProg doesn’t need to directly call any of the routines in thatUnit, you can “hide” the routines in thatUnit by omitting it from the uses clause:

```
unit thisUnit;
uses thatUnit;
...
program MyProg;
uses thisUnit, theOtherUnit;
...
```

In this example, thisUnit can call any of the routines in thatUnit, and MyProg can call any of the routines in thisUnit or theOtherUnit. MyProg cannot, however, call any of the routines in thatUnit because thatUnit does not appear in MyProg’s uses clause.

If you don’t put a uses clause in your program, Turbo Pascal links in the System standard unit anyway. This unit provides some of the standard Pascal routines as well as a number of Turbo Pascal-specific routines.

---

Referencing unit declarations

Once you include a unit in your program, all the constants, data types, variables, procedures, and functions declared in that unit’s interface become available to you. For example, suppose the following unit existed:

```
unit MyStuff;
interface
const
  MyValue = 915;

type
  MyStars = (Deneb,Antares,Betelgeuse);
var
  MyWord: string[20];
```
procedure SetMyWord(Star: MyStars);
function TheAnswer: Integer;
implementation
...
end.

What you see here is the unit's interface, the portion that is visible to (and used by) your program. Given this, you might write the following program:

program TestStuff;
uses MyStuff;
var
  I: Integer;
  AStar: MyStars;
begin
  Writeln(MyValue);
  AStar := Deneb;
  SetMyWord(AStar);
  Writeln(MyWord);
  I := TheAnswer;
  Writeln(I);
end.

Now that you have included the statement uses MyStuff in your program, you can refer to all the identifiers declared in the interface section in the interface of MyStuff (MyWord, MyValue, and so on). However, consider the following situation:

program TestStuff;
uses MyStuff;
const
  MyValue = 22;
var
  I: Integer;
  AStar: MyStars;
function TheAnswer: Integer;
begin
  TheAnswer := -1
end;
begin
  Writeln(MyValue);
  AStar := Deneb;
  SetMyWord(AStar);
  Writeln(MyWord);
  I := TheAnswer;
  Writeln(I);
end.
This program redefines some of the identifiers declared in MyStuff. It will compile and run, but will use its own definitions for MyValue and TheAnswer, since those were declared more recently than the ones in MyStuff.

You’re probably wondering whether there’s some way in this situation to still refer to the identifiers in MyStuff? Yes, preface each one with the identifier MyStuff and a period (.). For example, here’s yet another version of the earlier program:

```pascal
program TestStuff;
uses MyStuff;
const
  MyValue = 22;
var
  I: Integer;
  AStar: MyStars;
function TheAnswer: Integer;
begin
  TheAnswer := -1;
end;
begin
  WriteIn(MyStuff.MyValue);
  AStar := Deneb;
  SetMyWord(AStar);
  WriteIn(MyWord);
  I := MyStuff.TheAnswer;
  WriteIn(I);
end.
```

This program will give you the same answers as the first one, even though you’ve redefined MyValue and TheAnswer. Indeed, it would have been perfectly legal (although rather wordy) to write the first program as follows:

```pascal
program TestStuff;
uses MyStuff;
var
  I: Integer;
  AStar: MyStuff.MyStars;
begin
  WriteIn(MyStuff.MyValue);
  AStar := MyStuff.Deneb;
  MyStuff.SetMyWord(AStar);
  WriteIn(MyStuff.MyWord);
  I := MyStuff.TheAnswer;
  WriteIn(I);
end.
```
Note that you can preface any identifier—constant, data type, variable, or subprogram—with the unit name.

As of version 5.0, Turbo Pascal allows you to place a `uses` clause in a unit's implementation section. If present, the `uses` clause must immediately follow the `implementation` keyword, just like a `uses` clause in the interface section must immediately follow the `interface` keyword.

A `uses` clause in the implementation section allows you to further hide the inner details of a unit, since units used in the `implementation` section are not visible to users of the unit. More importantly, however, it also enables you to construct mutually dependent units.

Since units in Turbo Pascal need not be strictly hierarchical, you can make circular unit references. The next section provides an example that demonstrates the usefulness of circular references.

The following program demonstrates how two units can “use” each other. The main program, `Circular`, uses a unit named `Display`. `Display` contains one routine in its interface section, `WriteXY`, which takes three parameters: an $(x, y)$ coordinate pair and a text message to display. If the $(x, y)$ coordinates are onscreen, `WriteXY` moves the cursor to $(x, y)$ and displays the message there; otherwise, it calls a simple error-handling routine.

So far, there's nothing fancy here—`WriteXY` is taking the place of `Write`. Here's where the circular unit reference enters in: How is the error-handling routine going to display its error message? By using `WriteXY` again. Thus you have `WriteXY`, which calls the error-handling routine `ShowError`, which in turn calls `WriteXY` to put an error message onscreen. If your head is spinning in circles, let's look at the source code to this example, so you can see that it's really not that tricky.

The main program, `Circular`, clears the screen and makes three calls to `WriteXY`:

```pascal
program Circular;
{ Display text using WriteXY }
uses
  Crt, Display;
```
begin
ClrScr;
WriteXY(1, 1, 'Upper left corner of screen');
WriteXY(100, 100, 'Way off the screen');
WriteXY(81 - Length('Back to reality'), 15, 'Back to reality');
end.

Look at the \((x, y)\) coordinates of the second call to \texttt{WriteXY}. It's hard to display text at \((100, 100)\) on an 80x25 line screen. Next, let's see how \texttt{WriteXY} works. Here's the source to the \texttt{Display} unit, which contains the \texttt{WriteXY} procedure. If the \((x, y)\) coordinates are valid, it displays the message; otherwise, \texttt{WriteXY} displays an error message:

\begin{verbatim}
unit Display;
{ Contains a simple video display routine }
interface
procedure WriteXY(X, Y: Integer; Message: String);
implementation
uses
  Crt, Error;
procedure WriteXY(X, Y: Integer; Message: String);
begin
  if (X in [1..80]) and (Y in [1..25]) then
    begin
      GoToXY(X, Y);
      Write(Message);
    end
  else
    ShowError('Invalid WriteXY coordinates');
end;
end.
\end{verbatim}

The \texttt{ShowError} procedure called by \texttt{WriteXY} is declared in the following code in the \texttt{Error} unit. \texttt{ShowError} always displays its error message on the 25th line of the screen:

\begin{verbatim}
unit Error;
{ Contains a simple error-reporting routine }
interface
procedure ShowError(ErrMsg: String);
implementation
uses
  Display;
\end{verbatim}
procedure ShowError(ErrMsg: String);
begin
  WriteXY(1, 25, 'Error: ' + ErrMsg);
end;
end.

Notice that the uses clause in the implementation sections of both Display and Error refer to each other. These two units can refer to each other in their implementation sections because Turbo Pascal can compile complete interface sections for both. In other words, the Turbo Pascal compiler will accept a reference to partially compiled unit A in the implementation section of unit B, as long as both A and B's interface sections do not depend upon each other (and thus follow Pascal’s strict rules for declaration order).

What if you want to modify WriteXY and ShowError to take an additional parameter that specifies a rectangular window onscreen:

procedure WriteXY(SomeWindow: WindRec; X, Y: Integer; Message: String);
procedure ShowError(SomeWindow: WindRec; ErrMsg: String);

Remember these two procedures are in separate units. Even if you declared WindData in the interface of one, there would be no legal way to make that declaration available to the interface of the other. The solution is to declare a third module that contains only the definition of the window record:

unit WindData;
interface
type
  WindRec = record
    X1, Y1, X2, Y2: Integer;
    ForeColor, BackColor: Byte;
    Active: Boolean;
  end;
implementation
end.

In addition to modifying the code to WriteXY and ShowError to make use of the new parameter, the interface sections of both the Display and Error units can now “use” WindData. This approach is legal because unit WindData has no dependencies in its uses clause, and units Display and Error refer to each other only in their respective implementation sections.
The standard units

The file TURBO.TPL contains all the standard units except Graph and the compatibility units (Graph3 and Turbo3): System, Overlay, Crt, Dos, and Printer. These are units loaded into memory with Turbo Pascal; they're always readily available to you. You will normally keep the file TURBO.TPL in the same directory as TURBO.EXE (or TPC.EXE).

System

*System* contains all the standard and built-in procedures and functions of Turbo Pascal. Every Turbo Pascal routine that is not part of standard Pascal and that is not in one of the other units is in *System*. This unit is always linked into every program. The details of the *System* unit are described in Chapter 10 of the *Programmer's Guide*, “The System unit.”

Dos

*Dos* defines numerous Pascal procedures and functions that are equivalent to the most commonly used DOS calls, such as Exec, GetTime, SetTime, DiskSize, and so on. It also defines two low-level routines, MsDos and Intr, which allow you to directly invoke any MS-DOS call or system interrupt. Registers is the data type for the parameter to MsDos and Intr. Some other constants and data types are also defined.

The *Dos* unit is discussed in detail in Chapter 11 of the *Programmer's Guide*, “The Dos unit.”

Overlay

*Overlay* provides support for Turbo Pascal's powerful overlay system. Overlays are discussed in detail in Chapter 13 of the *Programmer's Guide*, “The Overlay unit.”

Crt

*Crt* provides a set of PC-specific declarations for input and output: constants, variables, and routines. You can use these to manipulate your text screen (do windowing, direct cursor addressing, text color and background). You can also do “raw” input from the keyboard and control the PC's sound chip. *Crt* is
Printer

*Printer* declares the text-file variable *Lst* and connects it to a device driver that allows you to send standard Pascal output to the printer using *Write* and *Writeln*. For example, once you include *Printer* in your program, you could do the following:

```pascal
Write(Lst, 'The sum of ', A:4, ' and ', B:4, ' is ');  
C := A + B;  
Writeln(Lst, C:8);
```

Graph

The *Graph* unit is not built into TURBO.TPL, but instead resides on the same disk with the .BGI and .CHR support files. Place GRAPH.TPU in the current directory or use the unit directory to specify the full path to GRAPH.TPU. (If you have a hard disk and you used the INSTALL program, your system is already set up so you can use *Graph*.)

*Graph* supplies a set of fast, powerful graphics routines that allow you to make full use of the graphics capabilities of your PC. It implements the device-independent Borland graphics handler, allowing support of CGA, EGA, Hercules, AT &T 400, MCGA, 3270 PC, and VGA and 8514 graphics.

Further explanations of *Graph* and the Borland Graphic Interface (BGI) may be found in Chapter 12 of the *Programmer's Guide*, "The Graph unit and the BGI."

Turbo3 and Graph3

These units are provided for backward compatibility only. *Turbo3* contains two variables and several procedures no longer supported by Turbo Pascal. *Graph3* supports the full set of graphics routines—basic, advanced, and turtlegraphics—from version 3.0. Full information on these units is included in the online file TURBO3.INT.

Now that you've been introduced to units, let's see about writing your own.
Writing your own units

Say you’ve written a unit called IntLib, stored it in a file called INTLIB.PAS, and compiled it to disk; the resulting code file will be called INTLIB.TPU. To use it in your program, you must include a uses statement to tell the compiler you’re using that unit. Your program might look like this:

```pascal
program MyProg;
uses IntLib;
```

Note that Turbo Pascal expects the unit code file to have the same name (up to eight characters) of the unit itself. If your unit name is MyUtilities, then Turbo is going to look for a file called MYUTILIT.PAS.

Compiling units

You compile a unit exactly the way you’d compile a program: Write it using the editor and select the Compile | Compile command (or press Alt-F9). However, instead of creating an .EXE file, Turbo Pascal will create a .TPU (Turbo Pascal Unit) file. You can then leave this file as is or merge it into TURBO.TPL using TPUMOVER.EXE.

In any case, you probably want to copy your .TPU files (along with their source) to the unit directory you specified in the Unit Directories input box (Options | Directories). That way, you can reference those files without having to have them in the current directory or in TURBO.TPL. (The Unit Directories input box lets you give multiple directories for the compiler to search for in unit files.)

You can only have one unit in a given source file; compilation stops when the final end statement is encountered.

To locate a unit specified in a uses clause, the compiler first checks the resident units—those units loaded into memory at startup from the TURBO.TPL file. If the unit is not among the resident units, the compiler assumes it must be on disk. The name of the file is assumed to be the unit name with extension .TPU. It is first searched for in the current directory, and then in the directories specified with the Options | Directories menu command or in a /U directive on the TPC command line. For instance, the construct
uses Memory;

where *Memory* is not a resident unit, causes the compiler to look for the file MEMORY.TPU in the current directory, and then in each of the unit directories.

When the Compile | Make and Compile | Build commands compile the units specified in a *uses* clause, the source files are searched for in the same way as the .TPU files, and the name of a given unit's source file is assumed to be the unit name with extension .PAS.

**An example**

Okay, now let's write a small unit. We'll call it *IntLib* and put in two simple integer routines—a procedure and a function:

```pascal
unit IntLib;
interface
procedure ISwap(var I, J: Integer);
function IMax(I, J: Integer): Integer;
implementation
procedure ISwap;
var
  Temp: Integer;
begin
  Temp := I; I := J; J := Temp;
end; { of proc ISwap }
function IMax;
begin
  if I > J then
    IMax := I
  else IMax := J;
end; { of func IMax }
end. { of unit IntLib }
```

Type this in, save it as the file INTLIB.PAS, then compile it to disk. The resulting unit code file is INTLIB.TPU. Move it to your unit directory (whenever that might happen to be) or leave it in the same directory as the program that follows. This next program uses the unit *IntLib*:

```pascal
program IntTest;
uses IntLib;
var
  A, B: Integer;
begin
  Write('Enter two integer values: ');  
  Readln(A, B);
```

---

*Chapter 3, Turbo Pascal units* 69
ISwap(A,B);
Writeln('A = ', A, ' B = ', B);
Writeln('The max is ', IMax(A,B));
end. { of program IntTest }

Congratulations! You’ve just created your first unit and written a program that uses it!

Units and large programs

Up until now, you’ve probably thought of units only as libraries—collections of useful routines to be shared by several programs. Another function of a unit, however, is to break up a large program into modules.

Two aspects of Turbo Pascal make this modular functionality of units work: (1) its tremendous speed in compiling and linking and (2) its ability to manage several code files simultaneously, such as a program and several units.

Typically, a large program is divided into units that group procedures by their function. For instance, an editor application could be divided into initialization, printing, reading and writing files, formatting, and so on. Also, there could be a “global” unit—one used by all other units, as well as the main program—that defines global constants, data types, variables, procedures, and functions.

The skeleton of a large program might look like this:

```
program Editor;
uses
  Dos,Crt,Printer                      { Standard units from TURBO.TPL }
  EditGlobals,                         { User-written units }
  EditInit,
  EditPrint,
  EditRead,EditWrite,
 >EditFormat;

  { Program’s declarations, procedures, and functions }
begin  { main program }
  end.  { of program Editor }
```

Note that the units in this program could either be in TURBO.TPL or in their own individual .TPU files. If the latter is true, then Turbo Pascal will manage your project for you. This means when you recompile program Editor using the compiler’s built-in make facility, Turbo Pascal will compare the dates of each .PAS and
Units as overlays

Sometimes, even the ability to have multiple units loaded isn’t enough to solve your memory problems. You might not have 640K to work with, or you may need to have large amounts of data in memory at the same time. In other words, you just can’t fit your entire program into memory at once.

Turbo Pascal offers a solution: overlays. An overlay is a chunk of program that is loaded into memory when needed, and unloaded when not. This allows you to bring in sections of a program only when you need them.

Overlays in Turbo Pascal are based on units: The smallest chunk of code that can be loaded or unloaded is an entire unit. You can define complex sets of overlays, specifying which units can or cannot be in memory at the same time. Best of all, with Turbo Pascal’s intelligent overlay manager, you don’t have to worry about loading or unloading the overlays yourself—it’s all done automatically.

You’ll learn more about overlays and how to set them up and use them in Chapter 13 of the *Programmer’s Guide*, “The Overlay unit.”

The TPUMOVER utility

Suppose you want to add a well-designed and thoroughly debugged unit to the library of standard units (TURBO.TPL) so that it’s automatically loaded into memory when you run the compiler. Is there any way to add to TURBO.TPL? Yes, by using the TPUMOVER.EXE utility.
You can find out more about TPUMOVER in the file UTILS.DOC in ONLINE.ZIP on your distribution disks.

You can also use TPUMOVER to remove units from the Turbo Pascal standard unit library file, reducing its size and the amount of memory it takes up when loaded.

As you've seen, it's really quite simple to write your own units. A well-designed, well-implemented unit simplifies program development; you solve the problems only once, not for each new program. Best of all, a unit provides a clean, simple mechanism for writing very large programs.
Object-oriented programming (OOP) is a method of programming that closely mimics the way all of us get things done. It is a natural evolution from earlier innovations to programming language design: It is more structured than previous attempts at structured programming; and it is more modular and abstract than previous attempts at data abstraction and detail hiding. Three main properties characterize an object-oriented programming language:

- **Encapsulation**: Combining a record with the procedures and functions that manipulate it to form a new data type—an object.
- **Inheritance**: Defining an object and then using it to build a hierarchy of descendant objects, with each descendant inheriting access to all its ancestors' code and data.
- **Polymorphism**: Giving an action one name that is shared up and down an object hierarchy, with each object in the hierarchy implementing the action in a way appropriate to itself.

Turbo Pascal's language extensions give you the full power of object-oriented programming: more structure and modularity, more abstraction, and reusability built right into the language. All these features add up to code that is more structured, extensible, and easy to maintain.

The challenge of object-oriented programming is that it requires you to set aside habits and ways of thinking about programming that have been standard for many years. Once you do that,
however, OOP is a simple, straightforward, superior tool for solving many of the problems that plague traditional programs.

A note to you who have done object-oriented programming in other languages: Put aside your previous impressions of OOP and learn Turbo Pascal's object-oriented features on their own terms. OOP is not one single way of programming; it is a continuum of ideas. In its object philosophy, Turbo Pascal is more like C++ than Smalltalk. Smalltalk is an interpreter, while from the beginning, Turbo Pascal has been a pure native code compiler. Native code compilers do things differently (and far more quickly) than interpreters. Turbo Pascal was designed to be a production development tool, not a research tool.

And a note to you who haven't any notion at all what OOP is about: That's just as well. Too much hype, too much confusion, and too many people talking about something they don't understand have greatly muddied the waters in recent years. Strive to forget what people have told you about OOP. The best way (in fact, the only way) to learn anything useful about OOP is to do what you're about to do: Sit down and try it yourself.

Objects?

Yes, objects. Look around you...there's one: the apple you brought in for lunch. Suppose you were going to describe an apple in software terms. The first thing you might be tempted to do is pull it apart: Let $S$ represent the area of the skin; let $J$ represent the fluid volume of juice it contains; let $F$ represent the weight of fruit inside; let $D$ represent the number of seeds....

Don't think that way. Think like a painter. You see an apple, and you paint an apple. The picture of an apple is not an apple; it's just a symbol on a flat surface. But it hasn't been abstracted into seven numbers, all standing alone and independent in a data segment somewhere. Its components remain together, in their essential relationships to one another.

Objects model the characteristics and behavior of the elements of the world we live in. They are the ultimate data abstraction so far.

An apple can be pulled apart, but once it's been pulled apart it's not an apple anymore. The relationships of the parts to the whole and to one another are plainer when everything is kept together.
Inheritance

The goal of science is to describe the workings of the universe. Much of the work of science, in furthering that goal, is simply the creation of family trees. When entomologists return from the Amazon with a previously unknown insect in a jar, their fundamental concern is working out where that insect fits into the giant chart upon which the scientific names of all other insects are gathered. There are similar charts of plants, fish, mammals, reptiles, chemical elements, subatomic particles, and external galaxies. They all look like family trees: a single overall category at the top, with an increasing number of categories beneath that single category, fanning out to the limits of diversity.

Within the category insect, for example, there are two divisions: insects with visible wings, and insects with hidden wings or no wings at all. Under winged insects is a larger number of categories: moths, butterflies, flies, and so on. Each category has numerous subcategories, and beneath those subcategories are even more subcategories (see Figure 4.1).

This classification process is called taxonomy. It's a good starting metaphor for the inheritance mechanism of object-oriented programming.

The questions a scientist asks in trying to classify a new animal or object are these: How is it similar to the others of its general class? How is it different? Each different class has a set of behaviors and characteristics that define it. A scientist begins at the top of a specimen's family tree and starts descending the branches, asking those questions along the way. The highest levels are the most general, and the questions the simplest: Wings or no wings? Each level is more specific than the one before it, and less general. Eventually the scientist gets to the point of counting hairs on the third segment of the insect's hind legs—specific indeed (and a good reason, perhaps, not to be an entomologist).
The important point to remember is that once a characteristic is defined, all the categories beneath that definition include that characteristic. So once you identify an insect as a member of the order diptera (flies), you needn't make the point that a fly has one pair of wings. The species of insect called flies inherits that characteristic from its order.

As you'll learn shortly, object-oriented programming is the process of building family trees for data structures. One of the important things object-oriented programming adds to traditional languages like Pascal is a mechanism by which data types inherit characteristics from simpler, more general types. This mechanism is inheritance.

Objects: records that inherit

In Pascal terms, an object is very much like a record, which is a wrapper for joining several related elements of data together under one name. In a graphics environment, you might gather together the X and Y coordinates of a position on the graphics screen and call it a record type named Location:

```
Location = record
  X, Y: Integer;
end;
```
Location here is a record type; that is, it's a template that the compiler uses to create record variables. A variable of type Location is an instance of type Location. The term instance is used now and then in Pascal circles, but it is used all the time by OOP people, and you'll do well to start thinking in terms of types and instances of those types.

With type Location you have it both ways: When you need to think of the X and Y coordinates separately, you can think of them separately as fields X and Y of the record. On the other hand, when you need to think of the X and Y coordinates working together to pin down a place on the screen, you can think of them collectively as Location.

Suppose you want to display a point of light at a position described on the screen by a Location record. In Pascal you might add a Boolean field indicating whether there is an illuminated pixel at a given location, and make it a new record type:

```pascal
Point = record
  X, Y: Integer;
  Visible: Boolean;
end;
```

You might also be a little more clever and retain record type Location by creating a field of type Location within type Point:

```pascal
Point = record
  Position: Location;
  Visible: Boolean;
end;
```

This works, and Pascal programmers do it all the time. One thing this method doesn't do is force you to think about the nature of what you're manipulating in your software. You need to ask questions like, "How does a point on the screen differ from a location on the screen?" The answer is this: A point is a location that lights up. Think back on the first part of that statement: A point is a location....

There you have it!

Implicit in the definition of a point is a location for that point. (Pixels exist only onscreen, after all.) Object-oriented programming recognizes that special relationship. Because all points must contain a location, type Point is a descendant type of type Location. Point inherits everything that Location has, and adds whatever is new about Point to make Point what it must be.
This process by which one type inherits the characteristics of another type is called *inheritance*. The inheritor is called a *descendant type*; the type that the descendant type inherits from is an *ancestor type*.

The familiar Pascal record types cannot inherit. Turbo Pascal, however, extends the Pascal language to support inheritance. One of these extensions is a new category of data structure, related to records but far more powerful. Data types in this new category are defined with a new reserved word: `object`. An object type can be defined as a complete, stand-alone type in the fashion of Pascal records, or it can be defined as a descendant of an existing object type by placing the name of the ancestor type in parentheses after the reserved word `object`.

In the graphics example you just looked at, the two related object types would be defined this way:

```pascal
type
  Location = object
    X, Y: Integer;
  end;

  Point = object (Location)
    Visible: Boolean;
  end;
```

Here, `Location` is the ancestor type, and `Point` is the descendant type. As you’ll see a little later, the process can continue indefinitely: You can define descendants of type `Point`, and descendants of `Point`’s descendant type, and so on. A large part of designing an object-oriented application lies in building this *object hierarchy* expressing the family tree of the objects in the application.

All the types eventually inheriting from `Location` are called `Location`’s descendant types, but `Point` is one of `Location`’s immediate descendants. Conversely, `Location` is `Point`’s immediate ancestor. An object type (just like a DOS subdirectory) can have any number of immediate descendants, but only one immediate ancestor.

Objects are closely related to records, as these definitions show. The new reserved word `object` is the most obvious difference, but there are numerous other differences, some of them quite subtle, as you’ll see later.

For example, the `X` and `Y` fields of `Location` are not explicitly written into type `Point`, but `Point` has them anyway, by virtue of
Instances of object types

Instances of object types are declared just as any variables are declared in Pascal, either as static variables or as pointer referents allocated on the heap:

```pascal
type
  PointPtr = ^Point;

var
  StatPoint: Point;  { Ready to go! }
  DynaPoint: PointPtr;  { Must allocate with New before use }
```

An object's fields

You access an object's data fields just as you access the fields of an ordinary record, either through the `with` statement or by dotting. For example,

```pascal
MyPoint.Visible := False;

with MyPoint do
begin
  X := 341;
  Y := 42;
end;
```

Good practice and bad practice

Don't forget: An object's inherited fields are not treated specially simply because they are inherited.

Even though you can access an object's fields directly, it's not an especially good idea to do so. Object-oriented programming principles require that an object's fields be left alone as much as possible. This restriction might seem arbitrary and rigid at first, but it's part of the big picture of OOP that is being built in this chapter. In time you'll see the sense behind this new definition of good programming practice, though there's some ground to cover...
An object's data fields are what an object knows; its methods are what an object does.

before it all comes together. For now, take it on faith: Avoid accessing object data fields directly.

So—how are object fields accessed? What sets them and reads them?

The answer is that an object's methods are used to access an object's data fields whenever possible. A method is a procedure or function declared within an object and tightly bonded to that object.

Methods

Methods are one of object-oriented programming’s most striking attributes, and they take some getting used to. Start by harkening back to that fond old necessity of structured programming, initializing data structures. Consider the task of initializing a record with this definition:

```pascal
Location = record
    X, Y: Integer;
end;
```

Most programmers would use a with statement to assign initial values to the X and Y fields:

```pascal
var
    MyLocation: Location;

with MyLocation do
begin
    X := 17;
    Y := 42;
end;
```

This works well, but it's tightly bound to one specific record instance, MyLocation. If more than one Location record needs to be initialized, you'll need more with statements that do essentially the same thing. The natural next step is to build an initialization procedure that generalizes the with statement to encompass any instance of a Location type passed as a parameter:
procedure InitLocation(var Target: Location; NewX, NewY: Integer);
begin
  with Target do
  begin
    X := NewX;
    Y := NewY;
  end;
end;

This does the job, all right—but if you’re getting the feeling that it’s a little more fooling around than it ought to be, you’re feeling the same thing that object-oriented programming’s early proponents felt.

It’s a feeling that implies that, well, you’ve designed procedure InitLocation specifically to serve type Location. Why, then, must you keep specifying what record type and instance InitLocation acts upon? There should be some way of welding together the record type and the code that serves it into one seamless whole.

Now there is. It’s called a method. A method is a procedure or function welded so tightly to a given type that the method is surrounded by an invisible with statement, making instances of that type accessible from within the method. The type definition includes the header of the method. The full definition of the method is qualified with the name of the type. Object type and object method are the two faces of this new species of structure called an object:

type
  Location = object
    X, Y: Integer;
    procedure Init(NewX, NewY: Integer);
  end;

procedure Location.Init(NewX, NewY: Integer);
begin
  X := NewX; { The X field of a Location object }
  Y := NewY; { The Y field of a Location object }
end;

Now, to ‘initialize an instance of type Location, you simply call its method as though the method were a field of a record, which in one very real sense it is:

var
  MyLocation: Location;

MyLocation.Init(17, 42); { Easy, no? }
Defining methods

The process of defining an object's methods is reminiscent of Turbo Pascal units. Inside an object, a method is defined by the header of the function or procedure acting as a method:

```pascal
type
    Location = object
        X, Y: Integer;
    procedure Init(InitX, InitY: Integer);
    function GetX: Integer;
    function GetY: Integer;
end;
```

One of the most important tenets of object-oriented programming is that the programmer should think of code and data together during program design. Neither code nor data exists in a vacuum. Data directs the flow of code, and code manipulates the shape and values of data.

When your data and code are separate entities, there's always the danger of calling the right procedure with the wrong data or the wrong procedure with the right data. Matching the two is the programmer's job, and while Pascal's strong typing does help, at best it can only say what doesn't go together.

Pascal says nothing, anywhere, about what does go together. If it's not in a comment or in your head, you take your chances.

By bundling code and data declarations together, an object helps keep them in sync. Typically, to get the value of one of an object's fields, you call a method belonging to that object that returns the value of the desired field. To set the value of a field, you call a method that assigns a new value to that field.

Like many aspects of object-oriented programming, respect for encapsulated data is a discipline you should always observe. It's better to access an object's data by using the methods it provides, instead of reading the data directly. Turbo Pascal lets you enforce encapsulation through the use of a **private** declaration in an object's declaration.

See “Private section” on page 87 for details on how to do this.
All data fields must be declared before the first method declaration.

As with procedure and function declarations in a unit’s interface section, method declarations within an object tell what a method does, but not how.

The how is defined outside the object definition, in a separate procedure or function declaration. When methods are fully defined outside the object, the method name must be preceded by the name of the object type that owns the method, followed by a period:

```pascal
procedure Location.Init(InitX, InitY: Integer);
begin
  X := InitX;
  Y := InitY;
end;

function Location.GetX: Integer;
begin
 GetX := X;
end;

function Location.GetY: Integer;
begin
 GetY := Y;
end;
```

Method definition follows the intuitive dotting method of specifying a record field. In addition to having a definition of `Location.GetX`, it would be completely legal to define a procedure named `GetX` without the identifier `Location` preceding it. However, the “outside” `GetX` would have no connection to the object type `Location` and would probably confuse the sense of the program as well.

Notice that nowhere in the previous methods is there an explicit with object do... construct. The data fields of an object are freely available to that object’s methods. Although they are separated in the source code, the method bodies and the object’s data fields really share the same scope.

This is why one of `Location`’s methods can contain the statement `GetY := Y` without any qualifier to `Y`. It’s because `Y` belongs to the object that called the method. When an object calls a method, there is

---

Chapter 4, Object-oriented programming
This example is not fully correct syntactically; it's here simply to give you a fuller appreciation for the special link between an object and its methods.

Explicit use of `Self` is legal, but you should avoid situations that require it.

an implicit statement to the effect with `myself` do method linking the object and its method in scope.

This implicit `with` statement is accomplished by the passing of an invisible parameter to the method each time any method is called. This parameter is called `Self`, and is actually a full 32-bit pointer to the object instance making the method call. The `GetY` method belonging to `Location` is roughly equivalent to the following:

```pascal
function Location.GetY(var Self: Location): Integer;
begin
 GetY := Self.Y;
end;
```

Is it important for you to be aware of `Self`? Ordinarily, no: Turbo Pascal's generated code handles it all automatically in virtually all cases. There are a few circumstances, however, when you might have to intervene inside a method and make explicit use of the `Self` parameter.

`Self` is actually an automatically declared identifier, and if you happen to find yourself in the midst of an identifier conflict within a method, you can resolve it by using the `Self` identifier as a qualifier to any data field belonging to the method's object:

```pascal
type
  MouseStat = record
    Active: Boolean;
    X, Y: Integer;
    LButton, RButton: Boolean;
    Visible: Boolean;
  end;

procedure Location.GoToMouse(MousePos: MouseStat);
begin
  Hide;
  with MousePos do
  begin
    Self.X := X;
    Self.Y := Y;
  end;
  Show;
end;
```
Methods implemented as externals in assembly language must take Self into account when they access method parameters on the stack. For more details on method call stack frames, see Chapter 18 in the Programmer's Guide.

Object data fields and method formal parameters

This example is necessarily simple, and the use of Self could be avoided simply by abandoning the use of the with statement inside Location.GoToMouse. You might find yourself in a situation inside a complex method where the use of with statements simplifies the logic enough to make Self worthwhile. The Self parameter is part of the physical stack frame for all method calls.

One consequence of the fact that methods and their objects share the same scope is that a method's formal parameters cannot be identical to any of the object's data fields. This is not some new restriction imposed by object-oriented programming, but rather the same old scoping rule that Pascal has always had. It's the same as not allowing the formal parameters of a procedure to be identical to the procedure's local variables:

```pascal
procedure CrunchIt(Crunchee: MyDataRec, Crunchby, ErrorCode: Integer);
var
    A, B: Char;
    ErrorCode: Integer; { This declaration causes an error! }
begin
    ...
end;
```

A procedure's local variables and its formal parameters share the same scope and thus cannot be identical. You'll get "Error 4: Duplicate identifier" if you try to compile something like this; the same error occurs if you attempt to give a method a formal parameter identical to any field in the object that owns the method.

The circumstances are a little different, since having procedure headers inside a data structure is a wrinkle new to Turbo Pascal, but the guiding principles of Pascal scoping have not changed at all.

Objects exported by units

It makes good sense to define objects in units, with the object type declaration in the interface section of the unit and the procedure bodies of the object type's methods defined in the implementation section.
Exported means "defined within the interface section of a unit."

Units can have their own private object type definitions in the implementation section, and such types are subject to the same restrictions as any types defined in a unit implementation section. An object type defined in the interface section of a unit can have descendant object types defined in the implementation section of the unit. In a case where unit B uses unit A, unit B can also define descendant types of any object type exported by unit A.

The object types and methods described earlier can be defined within a unit as shown in POINTS.PAS on your disk. To make use of the object types and methods defined in unit Points, you simply use the unit in your own program, and declare an instance of type Point in the var section of your program:

```pascal
program MakePoints;
uses Graph, Points;
var
  APoint: Point;
...
```

To create and show the point represented by APoint, you simply call APoint's methods, using the dot syntax:

```pascal
APoint.Init(151, 82);          { Initial X,Y at 151,82 }
APoint.Show;                   { APoint turns itself on }
APoint.MoveTo(163, 101);       { APoint moves to 163,101 }
APoint.Hide;                   { APoint turns itself off }
```

Objects can also be typed constants.

Objects, being very similar to records, can also be used inside with statements. In that case, naming the object that owns the method isn't necessary:

```pascal
with APoint do
begin
  Init(151, 82);               { Initial X,Y at 151,82 }
  Show;                        { APoint turns itself on }
  MoveTo(163, 101);            { APoint moves to 163,101 }
  Hide;                        { APoint turns itself off }
end;
```

Just as with records, objects can be passed to procedures as parameters and (as you'll see later on) can also be allocated on the heap.
In some circumstances you may have parts of an object declaration that you don't want to export. For example, you may want to provide objects for other programmers to use without letting them manipulate the object's data directly. To make it easy for you, Turbo Pascal allows you to specify private fields and methods within objects.

Private fields and methods are accessible only within the unit in which the object is declared. In the previous example, if the type Point had private fields, for example, they could only be accessed by code within the Points unit. Even though other parts of Point would be exported, the parts declared as private would be inaccessible.

Private fields and methods are declared just after regular fields and methods, following the optional `private` reserved word. Thus, the full syntax for an object declaration is

```pascal
type
NewObject = object(ancestor)
  fields; { these are public }
  methods; { these are public }
private
  fields; { these are private }
  methods; { these are private }
end;
```

Most of what's been said about objects so far has been from a comfortable, Turbo Pascal-ish perspective, since that's most likely where you are coming from. This is about to change, as you move on to OOP concepts with fewer precedents in standard Pascal programming. Object-oriented programming has its own particular mindset, due in part to OOP's origins in the (somewhat insular) research community, but also because the concept is truly and radically different.

One often amusing outgrowth of this is that OOP fanatics anthropomorphize their objects. Data structures are no longer passive buckets that you toss values into. In the new view of things, an object is looked upon as an actor on a stage, with a set of lines (methods) memorized. When you (the director) give the word, the actor recites from the script.
It can be helpful to think of the statement `APoint.MoveTo(242,118)` as giving an order to object `APoint`, saying “Move yourself to location 242,118.” The object is the central concept here. Both the list of methods and the list of data fields contained by the object serve the object. Neither code nor data is boss.

Objects aren’t being described as actors on a stage just to be cute. The object-oriented programming paradigm tries very hard to model the components of a problem as components, and not as logical abstractions. The odds and ends that fill our lives, from toasters to telephones to terry towels, all have characteristics (data) and behaviors (methods). A toaster’s characteristics might include the voltage it requires, the number of slices it can toast at once, the setting of the light/dark lever, its color, its brand, and so on. Its behaviors include accepting slices of bread, toasting slices of bread, and popping toasted slices back up again.

If you wanted to write a kitchen simulation program, what better way to do it than to model the various appliances as objects, with their characteristics and behaviors encoded into data fields and methods? It’s been done, in fact; the very first object-oriented language (Simula-67) was created as a language for writing such simulations.

This is the reason that object-oriented programming is so firmly linked in conventional wisdom to graphics-oriented environments. Objects should be simulations, and what better way to simulate an object than to draw a picture of it? Objects in Turbo Pascal should model components of the problem you’re trying to solve. Keep that in mind as you further explore Turbo Pascal’s object-oriented extensions.

Encapsulation

Declaring fields as `private` allows you to enforce access to those fields only through methods.

The welding of code and data together into objects is called *encapsulation*. If you’re thorough, you can provide enough methods so that a user of the object never has to access its fields directly. Like Smalltalk and other programming languages, Turbo Pascal lets you enforce encapsulation through the use of a `private` directive. In this example, we won’t specify a `private` section for fields and methods, but instead we will restrict ourselves to using methods in order to access the data we want.

*Location* and *Point* are written such that it is completely unnecessary to access any of their internal data fields directly:
type
Location = object
  X, Y: Integer;
  procedure Init(InitX, InitY: Integer);
  function GetX: Integer;
  function GetY: Integer;
end;

Point = object(Location)
  Visible: Boolean;
  procedure Init(InitX, InitY: Integer);
  procedure Show;
  procedure Hide;
  function IsVisible: Boolean;
  procedure MoveTo(NewX, NewY: Integer);
end;

There are only three data fields here: X, Y, and Visible. The MoveTo method loads new values into X and Y, and the GetX and GetY methods return the values of X and Y. This leaves no further need to access X or Y directly. Show and Hide toggle the Boolean Visible between True and False, and the IsVisible function returns Visible's current state.

Assuming an instance of type Point called APoint, you would use this suite of methods to manipulate APoint's data fields indirectly, like this:

    with APoint do
    begin
      Init(0, 0); { Init new point at 0,0 }
      Show; { Make the point visible }
    end;

Note that the object's fields are not accessed at all except by the object's methods.

Methods: no downside

Adding these methods bulks up Point a little in source form, but the Turbo Pascal smart linker strips out any method code that is never called in a program. You therefore shouldn't hang back from giving an object type a method that might or might not be used in every program that uses the object type. Unused methods cost you nothing in performance or .EXE file size—if they're not used, they're simply not there.
There are powerful advantages to being able to completely decouple `Point` from global references. If nothing outside the object "knows" the representation of its internal data, the programmer who controls the object can alter the details of the internal data representation—as long as the method headers remain the same.

Within some object, data might be represented as an array, but later on (perhaps as the scope of the application grows and its data volume expands), a binary tree might be recognized as a more efficient representation. If the object is completely encapsulated, a change in data representation from an array to a binary tree does not alter the object's use at all. The interface to the object remains completely the same, allowing the programmer to fine-tune an object's performance without breaking any code that uses the object.

People who first encounter Pascal often take for granted the flexibility of the standard procedure `WriteLn`, which allows a single procedure to handle parameters of many different types:

```pascal
WriteLn(CharVar);  { Outputs a character value }
WriteLn(IntegerVar);  { Outputs an integer value }
WriteLn(RealVar);  { Outputs a floating-point value }
```

Unfortunately, standard Pascal has no provision for letting you create equally flexible procedures of your own.

Object-oriented programming solves this problem through inheritance: When a descendant type is defined, the methods of the ancestor type are inherited, but they can also be overridden if desired. To override an inherited method, simply define a new method with the same name as the inherited method, but with a different body and (if necessary) a different set of parameters.

A simple example should make both the process and the implications clear. Let's define a descendant type to `Point` that draws a circle instead of a point on the screen:
type
Circle = object (Point)
  Radius: Integer;
  procedure Init(InitX, InitY: Integer; InitRadius: Integer);
  procedure Show;
  procedure Hide;
  procedure Expand(ExpandBy: Integer);
  procedure MoveTo(NewX, NewY: Integer);
  procedure Contract(ContractBy: Integer);
end;

procedure Circle.Init(InitX, InitY: Integer; InitRadius: Integer);
begin
  Point.Init(InitX, InitY);
  Radius := InitRadius;
end;

procedure Circle.Show;
begin
  Visible := True;
  Graph.Circle(X, Y, Radius);
end;

procedure Circle.Hide;
var
  TempColor: Word;
begin
  TempColor := Graph.GetColor;
  Graph.SetColor(GetBkColor);
  Visible := False;
  Graph.Circle(X, Y, Radius);
  Graph.SetColor(TempColor);
end;

procedure Circle.Expand(ExpandBy: Integer);
begin
  Hide;
  Radius := Radius + ExpandBy;
  if Radius < 0 then Radius := 0;
  Show;
end;

procedure Circle.Contract(ContractBy: Integer);
begin
  Expand(-ContractBy);
end;
procedure Circle.MoveTo(NewX, NewY: Integer);
begin
  Hide;
  X := NewX;
  Y := NewY;
  Show;
end;

A circle, in a sense, is a fat point: It has everything a point has (an X,Y location, a visible/invisible state) plus a radius. Object type Circle appears to have only the single field Radius, but don’t forget about all the fields that Circle inherits by being a descendant type of Point. Circle has X, Y, and Visible as well, even if you don’t see them in the type definition for Circle.

Since Circle defines a new field, Radius, initializing it requires a new Init method that initializes Radius as well as the inherited fields. Rather than directly assigning values to inherited fields like X, Y and Visible, why not reuse Point’s initialization method (illustrated by Circle.Init’s first statement). The syntax for calling an inherited method is Ancestor.Method, where Ancestor is the type identifier of an ancestral object type, and Method is a method identifier of that type.

Note that calling the method you override is not merely good style; it’s entirely possible that Point.Init (or Location.Init for that matter) performs some important, hidden initialization. By calling the overridden method, you ensure that the descendant object type includes its ancestor’s functionality. In addition, any changes made to the ancestor’s method automatically affects all its descendants.

After calling Point.Init, Circle.Init can then perform its own initialization, which in this case consists only of assigning Radius the value passed in InitRadius.

Instead of drawing and hiding your circle point by point, you can make use of the BGI Circle procedure. If you do, Circle also needs new Show and Hide methods that override those of Point. These rewritten Show and Hide methods appear in the example starting on page 90.

Dotting resolves the potential problems stemming from the name of the object type being the same as that of the BGI routine that draws the object type on the screen. Graph.Circle is also a completely unambiguous way of telling Turbo Pascal that you’re
referencing the Circle routine in GRAPH.TPU and not the Circle object type.

Whereas methods can be overridden, data fields cannot. Once you define a data field in an object hierarchy, no descendant type can define a data field with precisely the same identifier.

---

**Inheriting static methods**

One additional Point method is overridden in the earlier definition of Circle: MoveTo. If you're sharp, you might be looking at MoveTo and wondering why MoveTo doesn't use the Radius field, and why it doesn't make any BGI or other library calls specific to drawing circles. After all, the GetX and GetY methods are inherited all the way from Location without modification. Circle.MoveTo is also completely identical to Point.MoveTo. Nothing was changed other than to copy the routine and give it Circle's qualifier in front of the MoveTo identifier.

This example demonstrates a problem with objects and methods set up in this fashion. All the methods shown so far in connection with the Location, Point, and Circle object types are static methods.

The term static was chosen to describe methods that are not virtual. (You will learn about virtual methods shortly.) Virtual methods are in fact the solution to this problem, but in order to understand the solution you must first understand the problem.

The symptoms of the problem are these: Unless a copy of the MoveTo method is placed in Circle's scope to override Point's MoveTo, the method does not work correctly when it is called from an object of type Circle. If Circle invokes Point's MoveTo method, what is moved on the screen is a point rather than a circle. Only when Circle calls a copy of the MoveTo method defined in its own scope are circles hidden and drawn by the nested calls to Show and Hide.

Why so? It has to do with the way the compiler resolves method calls. When the compiler compiles Point's methods, it first encounters Point.Show and Point.Hide and compiles code for both into the code segment. A little later down the file it encounters Point.MoveTo, which calls both Point.Show and Point.Hide. As with any procedure call, the compiler replaces the source code references to Point.Show and Point.Hide with the addresses of their generated code in the code segment. Thus, when the code for
*Point.MoveTo* is called, it in turn calls the code for *Point.Show* and *Point.Hide* and everything's in phase.

So far, this scenario is all classic Turbo Pascal and would have been true (except for the nomenclature) since version 1.0. Things change, however, when you get into inheritance. When *Circle* inherits a method from *Point, Circle* uses the method exactly as it was compiled.

Look again at what *Circle* would inherit if it inherited *Point.MoveTo*:

```pascal
procedure Point.MoveTo(NewX, NewY: Integer);
begin
  Hide;  { Calls Point.Hide }
  X := NewX;
  Y := NewY;
  Show;   { Calls Point.Show }
end;
```

The comments were added to drive home the fact that when *Circle* calls *Point.MoveTo*, it also calls *Point.Show* and *Point.Hide*, not *Circle.Show* and *Circle.Hide*. *Point.Show* draws a point, not a circle. As long as *Point.MoveTo* calls *Point.Show* and *Point.Hide*, *Point.MoveTo* can’t be inherited. Instead, it must be overridden by a second copy of itself that calls the copies of *Show* and *Hide* defined within its scope; that is, *Circle.Show* and *Circle.Hide*.

The compiler’s logic in resolving method calls works like this: When a method is called, the compiler first looks for a method of that name defined within the object type. The *Circle* type defines methods named *Init*, *Show*, *Hide*, *Expand*, *Contract*, and *MoveTo*. If a *Circle* method were to call one of those five methods, the compiler would replace the call with the address of one of *Circle’s* own methods.

If no method by a name is defined within an object type, the compiler goes up to the immediate ancestor type, and looks within that type for a method of the name called. If a method by that name is found, the address of the ancestor's method replaces the name in the descendant’s method’s source code. If no method by that name is found, the compiler continues up to the next ancestor, looking for the named method. If the compiler hits the very first (top) object type, it issues an error message indicating that no such method is defined.
But when a static inherited method is found and used, you must remember that the method called is the method exactly as it was defined and compiled for the ancestor type. If the ancestor's method calls other methods, the methods called are the ancestor's methods, even if the descendant has methods that override the ancestor's methods.

The methods discussed so far are static methods. They are static for the same reason that static variables are static: The compiler allocates them and resolves all references to them at compile time. As you've seen, objects and static methods can be powerful tools for organizing a program's complexity.

Sometimes, however, they are not the best way to handle methods.

Problems like the one described in the previous section are due to the compile-time resolution of method references. The way out is to be dynamic—and resolve such references at run time. Certain special mechanisms must be in place for this to be possible, but Turbo Pascal provides those mechanisms in its support of virtual methods.

Virtual methods implement an extremely powerful tool for generalization called polymorphism. Polymorphism is Greek for "many shapes," and it is just that: A way of giving an action one name that is shared up and down an object hierarchy, with each object in the hierarchy implementing the action in a way appropriate to itself.

The simple hierarchy of graphic figures already described provides a good example of polymorphism in action, implemented through virtual methods.

Each object type in our hierarchy represents a different type of figure onscreen: a point or a circle. It certainly makes sense to say that you can show a point on the screen, or show a circle. Later on, if you were to define objects to represent other figures such as lines, squares, arcs, and so on, you could write a method for each that would display that object onscreen. In the new way of object-oriented thinking, you could say that all these graphic figure types had the ability to show themselves on the screen. That much they all have in common.
What is different for each object type is the way it must show itself to the screen. A point is drawn with a point-plotting routine that needs nothing more than an X,Y location and perhaps a color value. A circle needs an entirely separate graphics routine to display itself, taking into account not only X and Y, but a radius as well. Still further, an arc needs a start angle and an end angle, and a more complex drawing algorithm to take them into account.

Any graphic figure can be shown, but the mechanism by which each is shown is specific to each figure. One word, “Show,” is used to show (literally) many shapes.

That’s a good example of what polymorphism is, and virtual methods are how it is done in Turbo Pascal.

Early binding vs. late binding

The difference between a static method call and a virtual method call is the difference between a decision made now and a decision delayed. When you code a static method call, you are in essence telling the compiler, “You know what I want. Go call it.” Making a virtual method call, on the other hand, is like telling the compiler, “You don’t know what I want—yet. When the time comes, ask the instance.”

Think of this metaphor in terms of the MoveTo problem mentioned in the previous section. A call to Circle.MoveTo can only go to one place: the closest implementation of MoveTo up the object hierarchy. In that case, Circle.MoveTo would still call Point’s definition of MoveTo, since Point is the closest up the hierarchy from Circle. Assuming that no descendent type defined its own MoveTo to override Point’s MoveTo, any descendent type of Point would still call the same implementation of MoveTo. The decision can be made at compile time and that’s all that needs to be done.

When MoveTo calls Show, however, it’s a different story. Every figure type has its own implementation of Show, so which implementation of Show is called by MoveTo should depend entirely on what object instance originally called MoveTo. This is why the call to the Show method within the implementation of MoveTo must be a delayed decision: When the code for MoveTo is compiled, no decision as to which Show to call can be made. The information isn’t available at compile time, so the decision has to be deferred until run time, when the object instance calling MoveTo can be queried.
The process by which static method calls are resolved unambiguously to a single method by the compiler at compile time is *early binding*. In early binding, the caller and the callee are connected (bound) at the earliest opportunity, that is, at compile time. With *late binding*, the caller and the callee cannot be bound at compile time, so a mechanism is put into place to bind the two later on, when the call is actually made.

The nature of the mechanism is interesting and subtle, and you’ll see how it works a little later.

Object type compatibility

Inheritance somewhat changes Turbo Pascal’s type compatibility rules. In addition to everything else, a descendant type inherits type compatibility with all its ancestor types. This extended type compatibility takes three forms:

- between object instances
- between pointers to object instances
- between formal and actual parameters

In all three forms, however, it is critical to remember that type compatibility extends *only* from descendant to ancestor. In other words, descendant types can be freely used in place of ancestor types, but not vice versa.

Consider these declarations:

```pascal
type
  LocationPtr = ^Location;
  PointPtr = ^Point;
  CirclePtr = ^Circle;

var
  ALocation: Location;
  APoint: Point;
  ACircle: Circle;
  PLocation: LocationPtr;
  PPoint: PointPtr;
  PCircle: CirclePtr;
```

With these declarations, the following assignments are legal:

```pascal
ALocation := APoint;
APoint := ACircle;
ALocation := ACircle;
```

An ancestor object can be assigned an instance of any of its descendant types.
The reverse assignments are not legal.

This is a concept new to Pascal, and it might be a little hard to remember, at first, which way the type compatibility goes. Think of it this way: The source must be able to completely fill the destination. Descendant types contain everything their ancestor types contain by virtue of inheritance. Therefore a descendant type is either exactly the same size or (usually) larger than its ancestors, but never smaller. Assigning an ancestor object to a descendant object could leave some of the descendant's fields undefined after the assignment, which is dangerous and therefore illegal.

In an assignment statement, only the fields that the two types have in common are copied from the source to the destination. In the assignment statement

```
ALocation := ACircle;
```

only the X and Y fields of ACircle are copied to ALocation, since X and Y are all that types Circle and Location have in common.

Type compatibility also operates between pointers to object types, under the same rule as for instances of object types: Pointers to descendants can be assigned to pointers to ancestors. These pointer assignments are also legal:

```
PPoint := PCircle;
PLocation := PPoint;
PLocation := PCircle;
```

Again, the reverse assignments are not legal.

A formal parameter (either value or var) of a given object type can take as an actual parameter an object of its own, or any descendant type. Given this procedure header,

```
procedure DragIt(Target: Point);
```

actual parameters could legally be of type Point or Circle, but not type Location. Target could also be a var parameter; the same type compatibility rule applies.

However, keep in mind that there's a drastic difference between a value parameter and a var parameter: A var parameter is a pointer to the actual object passed as a parameter, whereas a value parameter is only a copy of the actual parameter. That copy, moreover, only includes the fields and methods included in the formal value parameter's type. This means the actual parameter is literally translated to the type of the formal parameter. A var
Polymorphic objects

In reading the previous section, you might have asked yourself: If any descendant type of a parameter's type can be passed in the parameter, how does the user of the parameter know which object type it is receiving? In fact, the user does not know, not directly. The exact type of the actual parameter is unknown at compile time. It could be any one of the object types descended from the var parameter type and is thus called a polymorphic object.

Now, exactly what are polymorphic objects good for? Primarily, this: *Polymorphic objects allow the processing of objects whose type is not known at compile time.* This whole notion is so new to the Pascal way of thinking that an example might not occur to you immediately. (You’ll be surprised, in time, at how natural it begins to seem. That’s when you’ll truly be an object-oriented programmer.)

Suppose you’ve written a graphics drawing toolbox that supports numerous types of figures: points, circles, squares, rectangles, curves, and so on. As part of the toolbox, you want to write a routine that drags a graphics figure around the screen with the mouse pointer.

The old way would have been to write a separate drag procedure for each type of graphics figure supported by the toolbox. You would have had to write *DragCircle, DragSquare, DragRectangle,* and so on. Even if the strong typing of Pascal allowed it (and don’t forget, there are always ways to circumvent strong typing), the differences between the types of graphics figures would seem to prevent a truly general dragging routine from being written.

After all, a circle has a radius but no sides, a square has one length of side, a rectangle two different lengths of side, and curves, arrgh....
At this point, clever Turbo Pascal hackers will step forth and say, do it this way: Pass the graphics figure record to procedure DragIt as the referent of a generic pointer. Inside DragIt, examine a tag field at a fixed offset inside the graphics figure record to determine what sort of figure it is, and then branch using a case statement:

```pascal
  case FigureIDTag of
    Point       : DragPoint;
    Circle      : DragCircle;
    Square      : DragSquare;
    Rectangle   : DragRectangle;
    Curve       : DragCurve;
    ...          
  end;
```

Well, placing seventeen small suitcases inside one enormous suitcase is a slight step forward, but what's the real problem with this way of doing things?

What if the user of the toolbox defines some new graphics figure type?

What indeed? What if the user designs traffic signs and wants to work with octagons for stop signs? The toolbox does not have an Octagon type, so DragIt would not have an Octagon label in its case statement, and would therefore refuse to drag the new Octagon figure. If it were presented to DragIt, Octagon would fall out in the case statement's else clause as an "unrecognized figure."

Plainly, building a toolbox of routines for sale without source code suffers from this problem: The toolbox can only work on data types that it "knows," that is, that are defined by the designers of the toolbox. The user of the toolbox is powerless to extend the function of the toolbox in directions unanticipated by the toolbox designers. What the user buys is what the user gets. Period.

The way out is to use Turbo Pascal's extended type compatibility rules for objects and design your application to use polymorphic objects and virtual methods. If a toolbox DragIt procedure is set up to work with polymorphic objects, it works with any objects defined within the toolbox—and any descendant objects that you define yourself. If the toolbox object types use virtual methods, the toolbox objects and routines can work with your custom graphics figures on the figures' own terms. A virtual method you define today is callable by a toolbox .TPU unit file that was
written and compiled a year ago. Object-oriented programming makes it possible, and virtual methods are the key.

Understanding how virtual methods make such polymorphic method calls possible requires a little background on how virtual methods are declared and used.

---

Virtual methods

A method is made virtual by following its declaration in the object type with the new reserved word `virtual`. Remember that if you declare a method in an ancestor type `virtual`, all methods of the same name in any descendant must also be declared `virtual` to avoid a compiler error.

Here are the graphics shape objects you've been seeing, properly virtualized:

```pascal
type
  Location = object
    X, Y: Integer;
    procedure Init(InitX, InitY: Integer);
    functionGetX: Integer;
    functionGetY: Integer;
  end;

Point = object(Location)
  Visible: Boolean;
  constructor Init(InitX, InitY: Integer);
  procedure Show; virtual;
  procedure Hide; virtual;
  function IsVisible: Boolean;
  procedure MoveTo(NewX, NewY: Integer);
end;

Circle = object(Point)
  Radius: Integer;
  constructor Init(InitX, InitY: Integer; InitRadius: Integer);
  procedure Show; virtual;
  procedure Hide; virtual;
  procedure Expand(ExpandBy: Integer); virtual;
  procedure Contract(ContractBy: Integer); virtual;
end;
```

Notice first of all that the `MoveTo` method shown in the last iteration of type `Circle` is gone from Circle's type definition. `Circle` no longer needs to override `Point`'s `MoveTo` method with an unmodified copy compiled within its own scope. Instead, `MoveTo` can now be inherited from `Point`, with all `MoveTo`'s nested method
calls going to Circle's methods rather than Point's, as happens in an all-static object hierarchy.

Also, notice the new reserved word constructor replacing the reserved word procedure for Point.Init and Circle.Init. A constructor is a special type of procedure that does some of the setup work for the machinery of virtual methods.

Every object type that has virtual methods must have a constructor.

The constructor must be called before any virtual method is called. Calling a virtual method without previously calling the constructor can cause system lockup, and the compiler has no way to check the order in which methods are called.

Each individual instance of an object must be initialized by a separate constructor call. It is not sufficient to initialize one instance of an object and then assign that instance to additional instances. The additional instances, while they might contain correct data, are not initialized by the assignment statements, and lock up the system if their virtual methods are called. For example:

```pascal
var
  QCircle, RCircle: Circle;  { create two instances of Circle }
begin
  QCircle.Init(600,100,30);   { call constructor for QCircle }
  RCircle := QCircle;         { RCircle is not valid! }
end.
```

What do constructors construct? Every object type has something called a virtual method table (VMT) in the data segment. The VMT contains the object type's size and, for each of its virtual methods, a pointer to the code implementing that method. What the constructor does is establish a link between the instance calling the constructor and the object type's VMT.

That's important to remember: There is only one virtual method table for each object type. Individual instances of an object type (that is, variables of that type) contain a link to the VMT—they do not contain the VMT itself. The constructor sets the value of that link to the VMT—which is why you can launch execution into nowhere by calling a virtual method before calling the constructor.
During program development, you might wish to take advantage of a safety net that Turbo Pascal places beneath virtual method calls. If the $R$ toggle is in its active state, {SR+}, all virtual method calls are checked for the initialization status of the instance making the call. If the instance making the call has not been initialized by its constructor, a range check run-time error occurs.

Once you've shaken out a program and are certain that no method calls from uninitialized instances are present, you can speed your code up somewhat by setting the $R$ toggle to its inactive state, {SR-}. Method calls from uninitialized instances will no longer be checked for, and will probably lock up your system if they're found.

Notice that both Point and Circle have methods named Show and Hide. All method headers for Show and Hide are tagged as virtual methods with the reserved word virtual. Once an ancestor object type tags a method as virtual, all its descendant types that implement a method of that name must tag that method virtual as well. In other words, a static method can never override a virtual method. If you try, a compiler error results.

You should also keep in mind that the method heading cannot change in any way downward in an object hierarchy once the method is made virtual. You might think of each definition of a virtual method as a gateway to all of them. For this reason, the headers for all implementations of the same virtual method must be identical, right down to the number and type of parameters. This is not the case for static methods; a static method overriding another can have different numbers and types of parameters as necessary.

To show how to use polymorphic objects with late binding in a Turbo Pascal program, let's return to the graphics figures unit described on page 86. The goal is to create a unit that exports several graphics figure objects (like Point and Circle) and a generalized means of dragging any of them around the screen. The unit, named Figures, is a simple implementation of the graphics toolbox discussed earlier. To demonstrate Figures, let's build a simple program that defines a new figure object type.
unknown to Figures and then uses virtual methods to drag that new figure type around the screen.

Think about how graphics figures are alike and how they differ. The differences are obvious, and all involve shapes and angles and curves drawn onscreen. In the simple graphics program we'll describe, figures displayed onscreen share these attributes:

- They have a location, given as X,Y. The point within a figure considered to lie at this X,Y position is called the figure's anchor point.
- They can be either visible or invisible, specified by a Boolean value of True (visible) or False (invisible).

If you recall the earlier examples, these are precisely the characteristics of the Location and Point object types. Point, in fact, represents a sort of "grandparent" type from which all graphics figure objects are descended.

The rationale demonstrates an important principle of object-oriented programming: In defining a hierarchy of object types, gather all common attributes into a single type and allow the hierarchy of types to inherit all common elements from that type.

Type Point acts as a template from which its descendant object types can take elements common to all types in the hierarchy. In this example, no object of type Point is ever actually drawn to the screen, though no harm would come of doing so. (Calling Point.Show would obviously display a point on the screen.) An object type specifically designed to provide inheritable characteristics for its descendants is called an abstract object type.

The point of an abstract type is to have descendants, not instances.

Go back to page 101 and read Point over once more, this time as a compendium of all the things that graphics figures have in common. Point inherits X and Y from the even earlier Location type, but Point contains X and Y nonetheless, and can bequeath them to its descendant types. Note that none of Point's methods address the shape of a figure, but all figures can be visible or invisible and can be moved around on the screen.

Point also has an important function as a "broadcasting station" for changes to the object hierarchy as a whole. If some new feature is devised that applies to all graphics figures (color support, for example), it can be added to all object types descended from Point simply by adding the new features to Point. The new features are
instantly callable from any of Point's descendant types. A method for moving a figure to the current position of the mouse pointer, for example, could be added to Point without changing any figure-specific methods, since such a method would only affect the two fields X and Y.

Obviously, if the new feature must be implemented differently for different figures, there must be a whole family of figure-specific virtual methods added to the hierarchy, each method overriding the one belonging to its immediate ancestor. Color, for example, would require minor changes to Show and Hide up and down the line, since the syntax of many GRAPH.TPU drawing routines depends on how drawing color is specified.

Procedure or method?

A major goal in designing the FIGURES.PAS unit is to allow users of the unit to extend the object types defined in the unit—and still make use of all the unit's features. It is an interesting challenge to create some means of dragging an arbitrary graphics figure around the screen in response to user input.

There are two ways to go about it. The way that might first occur to traditional Pascal programmers is to have FIGURES.PAS export a procedure that takes a polymorphic object as a var parameter, and then drags that object around the screen. Such a procedure is shown here:

```pascal
procedure DragIt(var AnyFigure: Point; DragBy: Integer);
var
  DeltaX, DeltaY: Integer;
  FigureX, FigureY: Integer;
begin
  AnyFigure.Show;  { Display figure to be dragged }
  FigureX := AnyFigure.GetX;  { Get the initial X,Y of figure }
  FigureY := AnyFigure.GetY;

  { This is the drag loop }
  while GetDelta(DeltaX, DeltaY) do
  begin
    FigureX := FigureX + (DeltaX * DragBy);
    FigureY := FigureY + (DeltaY * DragBy);
    { And tell the figure to move }
    AnyFigure.MoveTo(FigureX, FigureY);
  end;
end;
```

Chapter 4, Object-oriented programming
DragIt calls an additional procedure, GetDelta, that obtains some sort of change in X and Y from the user. It could be from the keyboard, or from a mouse, or a joystick. (For simplicity’s sake, our example obtains input from the arrow keys on the keypad.)

What’s important to notice about DragIt is that any object of type Point or any type descended from Point can be passed in the AnyFigure var parameter. Instances of Point or Circle, or any type defined in the future that inherits from Point or Circle, can be passed without complication in AnyFigure.

How does DragIt’s code know what object type is actually being passed? It doesn’t—and that’s OK. DragIt only references identifiers defined in type Point. By inheritance, those identifiers are also defined in any descendant of type Point. The methods GetX, GetY, Show, and MoveTo are just as truly present in type Circle as in type Point, and would be present in any future type defined as a descendant of either.

GetX, GetY, and MoveTo are static methods, which means that DragIt knows the procedure address of each at compile time. Show, on the other hand, is a virtual method. There is a different implementation of Show for both Point and Circle—and DragIt does not know at compile time which implementation is to be called. In brief, when DragIt is called, DragIt looks up the address of the correct implementation of Show in the VMT of the instance passed in AnyFigure. If the instance is a Circle, DragIt calls Circle.Show. If the instance is a Point, DragIt calls Point.Show. The decision as to which implementation of Show is called is not made until run time, and not, in fact, until the moment in the program when DragIt must call virtual method Show.

Now, DragIt works quite well, and if it is exported by the toolbox unit, it can drag any descendant type of Point around the screen, whether that type existed when the toolbox was compiled or not. But you have to think a little further: If any object can be dragged around the screen, why not make dragging a feature of the graphics objects themselves?

In other words, why not make DragIt a method?

Make it a method!

Indeed. Why pass an object to a procedure to drag the object around the screen? That’s old-school thinking. If a procedure can be written to drag any graphics figure object around the screen,
then the graphics figure objects ought to be able to drag themselves around the screen.

In other words, procedure DragIt really ought to be method Drag.

Adding a new method to an existing object hierarchy involves a little thought. How far up the hierarchy should the method be placed? Think about the utility provided by the method and decide how broadly applicable that utility is. Dragging a figure involves changing the location of the figure in response to input from the user. Metaphorically, you might think of a Drag method as MoveTo with an internal power source. In terms of inheritability, it sits right beside MoveTo—any object to which MoveTo is appropriate should also inherit Drag. Drag should thus be added to our abstract object type, Point, so that all Point's descendants can share it.

Does Drag need to be virtual? The litmus test for making any method virtual is whether the functionality of the method is expected to change somewhere down the hierarchy tree. Drag is a closed-ended sort of feature. It only manipulates the X,Y position of a figure, and one doesn't imagine that it would become more than that. Therefore, it probably doesn't need to be virtual.

Still, you should use caution in any such decision: If you don't make Drag virtual, you lock out all opportunities for users of FIGURES.PAS to alter it in their efforts to extend FIGURES.PAS. You might not be able to imagine the circumstances under which a user might want to rewrite Drag. That doesn't for a moment mean that such circumstances will not arise.

For example, Drag has a joker in it that tips the balance in favor of its being virtual: It deals with event handling, that is, the interception of input from devices like the keyboard and mouse, which occur at unpredictable times yet must be handled when they occur. Event handling is a messy business, and often very hardware-specific. If your user has some input device that does not meld well with Drag as you present it, the user will be helpless to rewrite Drag. Don't burn any bridges: Make Drag virtual.

The process of converting DragIt to a method and adding the method to Point is almost trivial. Within the Point object definition, Drag is just another method header:
Point = object (Location)
  Visible: Boolean;
  constructor Init (InitX, InitY: Integer);
  procedure Show; virtual;
  procedure Hide; virtual;
  function IsVisible: Boolean;
  procedure MoveTo (NewX, NewY: Integer);
  procedure Drag (DragBy: Integer); virtual;
end;

The position of Drag's method header in the Point object definition is unimportant. Remember, methods can be declared in any order, but data fields must be defined before the first method declaration.

Changing the procedure DragIt to the method Drag is almost entirely a matter of applying Point's scope to DragIt. In the DragIt procedure, you had to specify AnyFigure.Show, AnyFigure.GetX, and so on. Drag is now a part of Point, so you no longer have to qualify method names. AnyFigure.GetX is now simply GetX, and so on. And of course, the AnyFigure var parameter is banished from the parameter line. The implied Self parameter now tells you which object instance is calling Drag.

By now, you should be thinking in terms of building functionality into objects in the form of methods rather than building procedures and passing objects to them as parameters. Ultimately you'll come to design programs in terms of activities that objects can do, rather than as collections of procedure calls that act upon passive data.

It's a whole new world.

---

The important thing to notice about toolbox units like FIGURES.PAS is that the object types and methods defined in the unit can be distributed to users in linkable .TPU form only, without source code. (Only a listing of the interface portion of the unit need be released.) Using polymorphic objects and virtual methods, the users of the .TPU file can still add features to it to suit their needs.

This novel notion of taking someone else's program code and adding functionality to it without benefit of source code is called extensibility. Extensibility is a natural outgrowth of inheritance: You inherit everything that all your ancestor types have, and then
you add what new capability you need. Late binding lets the new meld with the old at run time, so the extension of the existing code is seamless and costs you no more in performance than a quick trip through the virtual method table.

FIGDEMO.PAS (on your disk) makes use of the Figures unit, and extends it by creating a new graphics figure object, Arc, as a descendant type of Circle. The object Arc could have been written long after FIGURES.PAS was compiled, and yet an object of type Arc can make use of inherited methods like MoveTo or Drag without any special considerations. Late binding and Arc's virtual methods allows the Drag method to call Arc's Show and Hide methods even though those methods might have been written long after Point.Drag itself was compiled.

Static or virtual methods

In general, you should make methods virtual. Use static methods only when you want to optimize for speed and memory efficiency. The tradeoff, as you've seen, is in extensibility.

Let's say you are declaring an object named Ancestor, and within Ancestor you are declaring a method named Action. How do you decide whether Action should be virtual or static? Here's the rule of thumb: Make Action virtual if there is a possibility that some future descendant of Ancestor will override Action, and you want that future code to be accessible to Ancestor.

Now apply this rule to the graphics objects you've seen in this chapter. In this case, Point is the ancestor object type, and you must decide whether to make its methods static or virtual. Let's consider its Show, Hide, and MoveTo methods. Since each different type of figure has its own means of displaying and erasing itself, Show and Hide are overridden by each descendant figure. Moving a graphics figure, however, seems to be the same for all descendants: Call Hide to erase the figure, change its X,Y coordinates, and then call Show to redisplay the figure in its new location. Since this MoveTo algorithm can be applied to any figure with a single anchor point at X,Y, it's reasonable to make Point.MoveTo a static method that is inherited by all descendants of Point; but Show and Hide are overridden and must be virtual so that Point.MoveTo can call its descendants' Show and Hide methods.

On the other hand, remember that if an object has any virtual methods, a VMT is created for that object type in the data segment...
and every object instance has a link to the VMT. Every call to a virtual method must pass through the VMT, while static methods are called directly. Though the VMT lookup is very efficient, calling a method that is static is still a little faster than calling a virtual one. And if there are no virtual methods in your object, then there is no VMT in the data segment and—more significantly—no link to the VMT in every object instance.

The added speed and memory efficiency of static methods must be balanced against the flexibility that virtual methods allow: extension of existing code long after that code is compiled. Keep in mind that users of your object type might think of ways to use it that you never dreamed of, which is, after all, the whole point.

---

**Dynamic objects**

The use of the word *static* here does not relate in any way to static methods.

All the object examples shown so far have had static instances of object types that were named in a `var` declaration and allocated in the data segment and on the stack.

```pascal
var
    ACircle: Circle;
```

Objects can be allocated on the heap and manipulated with pointers, just as the closely related record types have always been in Pascal. Turbo Pascal includes some powerful extensions to make dynamic allocation and deallocation of objects easier and more efficient.

Objects can be allocated as pointer referents with the `New` procedure:

```pascal
var
    PCircle: ^Circle;

New(PCircle);
```

As with record types, `New` allocates enough space on the heap to contain an instance of the pointer's base type, and returns the address of that space in the pointer.

If the dynamic object contains virtual methods, it must then be initialized with a constructor call before any calls are made to its methods:

```pascal
PCircle^.Init(600, 100, 30);
```
Allocation and initialization with New

Method calls can then be made normally, using the pointer name and the reference symbol `^` (a caret) in place of the instance name that would be used in a call to a statically allocated object:

```
OldXPosition := PCircle^ .GetX;
```

Turbo Pascal extends the syntax of `New` to allow a more compact and convenient means of allocating space for an object on the heap and initializing the object with one operation. `New` can now be invoked with two parameters: the pointer name as the first parameter, and the constructor invocation as the second parameter:

```
New(PCircle, Init(600, 100, 30));
```

When you use this extended syntax for `New`, the constructor `Init` actually performs the dynamic allocation, using special entry code generated as part of a constructor's compilation. The instance name cannot precede `Init`, since at the time `New` is called, the instance being initialized with `Init` does not yet exist. The compiler identifies the correct `Init` method to call through the type of the pointer passed as the first parameter.

`New` has also been extended to allow it to act as a function returning a pointer value. The parameter passed to `New` is the type of the pointer to the object rather than the pointer variable itself:

```pascal
type
    ArcPtr = ^Arc;

var
    PArc: ArcPtr;
    PArc := New(ArcPtr);
```

Note that with version, the function-form extension to `New` applies to all data types, not only to object types:

```pascal
type
    CharPtr = ^Char;  { Char is not an object type... }

var
    PChar: CharPtr;
    PChar := New(CharPtr);
```
Fail helps you do error recovery in constructors; see the section “Constructor error recovery” in Chapter 17 of the Programmer’s Guide.

Disposing dynamic objects

Just like traditional Pascal records, objects allocated on the heap can be deallocated with Dispose when they are no longer needed:

Dispose(PCircle);

There can be more to getting rid of an unneeded dynamic object than just releasing its heap space, however. An object can contain pointers to dynamic structures or objects that need to be released or “cleaned up” in a particular order, especially when elaborate dynamic data structures are involved. Whatever needs to be done to clean up a dynamic object in an orderly fashion should be gathered together in a single method so that the object can be eliminated with one method call:

MyComplexObject.Done;

The Done method should encapsulate all the details of cleaning up its object and all the data structures and objects nested within it.

It is legal and often useful to define multiple cleanup methods for a given object type. Complex objects might need to be cleaned up in different ways depending on how they were allocated or used, or depending on what mode or state the object was in when it was cleaned up.

Destructors

Turbo Pascal provides a special type of method called a destructor for cleaning up and disposing of dynamically allocated objects. A destructor combines the heap deallocation step with whatever other tasks are necessary for a given object type. As with any method, multiple destructors can be defined for a single object type.

The function form of New, like the procedure form, can also take the object type’s constructor as a second parameter:

PArc := New(ArcPtr, Init(600, 100, 25, 0, 90));

A parallel extension to Dispose has been defined for Turbo Pascal, as fully explained in the following sections.
A destructor is defined with all the object's other methods in the object type definition:

```pascal
Point = object(Location)
  Visible: Boolean;
  Next: PointPtr;
  constructor Init(InitX, InitY: Integer);
  destructor Done; virtual;
  procedure Show; virtual;
  procedure Hide; virtual;
  function IsVisible: Boolean;
  procedure MoveTo(NewX, NewY: Integer);
  procedure Drag(DragBy: Integer); virtual;
end;
```

Destructors can be inherited, and they can be either static or virtual. Because different shutdown tasks are usually required for different object types, it is a good idea always to make destructors virtual, so that in every case the correct destructor is executed for its object type.

Keep in mind that the reserved word `destructor` is not needed for every cleanup method, even if the object type definition contains virtual methods. Destructors really operate only on dynamically allocated objects. In cleaning up a dynamically allocated object, the destructor performs a special service: It guarantees that the correct number of bytes of heap memory are always released. There is, however, no harm in using destructors with statically allocated objects; in fact, by not giving an object type a destructor, you prevent objects of that type from getting the full benefit of Turbo Pascal's dynamic memory management.

Destructors really come into their own when polymorphic objects must be cleaned up and their heap allocation released. A polymorphic object is an object that has been assigned to an ancestor type by virtue of Turbo Pascal's extended type compatibility rules. In the running example of graphics figures, an instance of object type `Circle` assigned to a variable of type `Point` is an example of a polymorphic object. These rules govern pointers to objects as well; a pointer to `Circle` can be freely assigned to a pointer to type `Point`, and the referent of that pointer is also a polymorphic object.

The term `polymorphic` is appropriate because the code using the object doesn't know at compile time precisely what type of object is on the end of the string—only that the object is one of a hierarchy of objects descended from the specified type.
The size of object types differ, obviously. So when it comes time to clean up a polymorphic object allocated on the heap, how does `Dispose` know how many bytes of heap space to release? No information on the size of the object can be gleaned from a polymorphic object at compile time.

The destructor solves the problem by going to the place where the information is stored: in the instance variable's VMT. In every object type's VMT is the size in bytes of the object type. The VMT for any object is available through the invisible `Self` parameter passed to the method on any method call. A destructor is just a special kind of method, and it receives a copy of `Self` on the stack when an object calls it. So while an object might be polymorphic at compile time, it is never polymorphic at run time, thanks to late binding.

To perform this late-bound memory deallocation, the destructor must be called as part of the extended syntax for the `Dispose` procedure:

```pascal
Dispose(PPoint, Done);
```

(Calling a destructor outside of a `Dispose` call does no automatic deallocation at all.) What happens here is that the destructor of the object pointed to by `PPoint` is executed as a normal method call. As the last thing it does, however, the destructor looks up the size of its instance type in the instance's VMT, and passes the size to `Dispose`. `Dispose` completes the shutdown by deallocating the correct number of bytes of heap space that had previously belonged to `PPoint`. The number of bytes released is correct whether `PPoint` points to an instance of type `Point` or to one of `Point`'s descendant types like `Circle` or `Arc`.

Note that the destructor method itself can be empty and still perform this service:

```pascal
destructor AnObject.Done;
begin
end;
```

What performs the useful work in this destructor is not the method body but the epilog code generated by the compiler in response to the reserved word `destructor`. In this, it is similar to a unit that exports nothing, but performs some "invisible" service by executing an initialization section before program startup. The action is all behind the scenes.
An example of dynamic object allocation

The final example program provides some practice in the use of objects allocated on the heap, including the use of destructors for object deallocation. The program shows how a linked list of graphics objects might be created on the heap and cleaned up using destructor calls when they are no longer required.

Building a linked list of objects requires that each object contain a pointer to the next object in the list. Type $Point$ contains no such pointer. The easy way out would be to add a pointer to $Point$, and in doing so ensure that all $Point$'s descendant types also inherit the pointer. However, adding anything to $Point$ requires that you have the source code for $Point$, and as said earlier, one advantage of object-oriented programming is the ability to extend existing objects without necessarily being able to recompile them.

The solution that requires no changes to $Point$ creates a new object type not descended from $Point$. Type $List$ is a very simple object whose purpose is to head up a list of $Point$ objects. Because $Point$ contains no pointer to the next object in the list, a simple record type, $Node$, provides that service. $Node$ is even simpler than $List$, in that it is not an object, has no methods, and contains no data except a pointer to type $Point$ and a pointer to the next node in the list.

$List$ has a method that allows it to add new figures to its linked list of $Node$ records by inserting a new instance of $Node$ immediately after itself, as a referent to its Nodes pointer field. The $Add$ method takes a pointer to a $Point$ object, rather than a $Point$ object itself. Because of Turbo Pascal's extended type compatibility, pointers to any type descended from $Point$ can also be passed in the $Item$ parameter to $List.Add$.

Program $ListDemo$ declares a static variable, $AList$, of type $List$, and builds a linked list with three nodes. Each node points to a different graphics figure that is either a $Point$ or one of its descendants. The number of bytes of free heap space is reported before any of the dynamic objects are created, and then again after all have been created. Finally, the whole structure, including the three $Node$ records and the three $Point$ objects, are cleaned up and removed from the heap with a single destructor call to the static $List$ object, $AList$. 
Disposing of a complex data structure on the heap

This destructor, *List.Done*, is worth a close look. Shutting down a *List* object involves disposing of three different kinds of structures: the polymorphic graphics figure objects in the list, the *Node* records that hold the list together, and (if it is allocated on the heap) the *List* object that heads up the list. The whole process is invoked by a single call to *AList*'s destructor:

```
AList.Done;
```

The code for the destructor merits examination:

```
destructor List.Done;
var
  N: NodePtr;
begin
  while Nodes <> nil do
    begin
      N := Nodes;
      Dispose(Node.Item, Done);
      Nodes := Node.Next;
      Dispose(N);
    end;
end;
```

The list is cleaned up from the list head by the "hand-over-hand" algorithm, metaphorically similar to pulling in the string of a kite: Two pointers, the *Nodes* pointer within *AList* and a working pointer *N*, alternate their grasp on the list while the first item in
the list is disposed of. A dispose call deallocates storage for the first `Point` object in the list (`Item^`); then `Nodes` is advanced to the next `Node` record in the list by the statement `Nodes := N^.Next;`; the `Node` record itself is deallocated; and the process repeats until the list is gone.

The important thing to note in the destructor `Done` is the way the `Point` objects in the list are deallocated:

```pascal
Dispose(N^.Item, Done);
```

Here, `N^.Item` is the first `Point` object in the list, and the `Done` method called is its destructor. Keep in mind that the actual type of `N^.Item^` is not necessarily `Point`, but could as well be any descendant type of `Point`. The object being cleaned up is a polymorphic object, and no assumptions can be made about its actual size or exact type at compile time. In the earlier call to `Dispose`, once `Done` has executed all the statements it contains, the "invisible" epilog code in `Done` looks up the size of the object instance being cleaned up in the object's VMT. `Done` passes that size to `Dispose`, which then releases the exact amount of heap space the polymorphic object actually occupied.

Remember that polymorphic objects must be cleaned up this way, through a destructor call passed to `Dispose`, if the correct amount of heap space is to be reliably released.

In the example program, `AList` is declared as a static variable in the data segment. `AList` could as easily have been itself allocated on the heap, and anchored to reality by a pointer of type `ListPtr`. If the head of the list had been a dynamic object too, disposing of the structure would have been done by a destructor call executed within `Dispose`:

```pascal
var
    PList: ListPtr;
...
Dispose(PList, Done);
```

Here, `Dispose` calls the destructor method `Done` to clean up the structure on the heap. Then, once `Done` is finished, `Dispose` deallocates storage for `PList`'s referent, removing the head of the list from the heap as well.

`LISTDEMO.PAS` (on your disk) uses the same `FIGURES.PAS` unit described on page 108. It implements an `Arc` type as a descendant of `Point`, creates a `List` object heading up a linked list of three polymorphic objects compatible with `Point`, and then disposes of the
whole dynamic data structure with a single destructor call to
AList.Done.

Where to now?

As with any aspect of computer programming, you don’t get
better at object-oriented programming by reading about it; you
get better at it by doing it. Most people, on first exposure to
object-oriented programming, are heard to mutter “I don’t get it”
under their breath. The “Aha!” comes later, when in the midst of
putting their own objects in place, the whole concept comes
together in the sort of perfect moment we used to call an epi-
phany. Like the face of woman emerging from a Rorschach
inkblot, what was obscure before at once becomes obvious, and
from then on it’s easy.

The best thing to do for your first object-oriented project is to take
the FIGURES.PAS unit (you have it on disk) and extend it. Points,
circles, and arcs are by no means enough. Create objects for lines,
rectangles, and squares. When you’re feeling more ambitious,
create a pie-chart object using a linked list of individual pie-slice
figures.

One more subtle challenge is to implement objects with relative
position. A relative position is an offset from some base point,
expressed as a positive or negative difference. A point at relative
coordinates \(-17,42\) is 17 pixels to the left of the base point, and 42
pixels down from that base point. Relative positions are necessary
to combine figures effectively into single larger figures, since
multiple-figure combination figures cannot always be tied
together at each figure’s anchor point. Better to define an \(RX\) and
\(RY\) field in addition to anchor point \(X,Y\), and have the final posi-
tion of the object onscreen be the sum of its anchor point and
relative coordinates.

Once you’ve had your “Aha!” start building object-oriented
concepts into your everyday programming chores. Take some
existing utilities you use every day and rethink them in object
oriented terms. Take another look at your hodgepodge of
procedure libraries and try to see the objects in them—then
rewrite the procedures in object form. You’ll find that libraries of
objects are much easier to reuse in future projects. Very little of
your initial investment in programming effort will ever be
wasted. You will rarely have to rewrite an object from scratch. If it
Conclusion

Object-oriented programming is a direct response to the complexity of modern applications, complexity that has often made many programmers throw up their hands in despair. Inheritance and encapsulation are extremely effective means for managing complexity. (It's the difference between having ten thousand insects classified in a taxonomy chart, and ten thousand insects all buzzing around your ears.) Far more than structured programming, object-orientation imposes a rational order on software structures that, like a taxonomy chart, imposes order without imposing limits.

Add to that the promise of the extensibility and reusability of existing code, and the whole thing begins to sound almost too good to be true. Impossible, you think?

Hey, this is Turbo Pascal. "Impossible" is undefined.
Debugging Turbo Pascal programs

Turbo Pascal's superb development environment includes automatic project management, program modularity, high-speed compilation, and easy-to-use overlays. Yet with all that, your program can still have bugs, or errors, that keep it from working correctly.

Turbo Pascal gives you the tools you need to debug your program, which means to find and remove all the errors to get it running. Turbo Pascal also makes it easy to locate and fix compiler and run-time errors. And it lets you enable or disable automatic error checking at run time.

Turbo Pascal comes with a powerful, flexible source-level debugger that allows you to execute your program one line at a time, viewing expressions and modifying variables as you go. This debugger is built into the Turbo Pascal IDE; you can edit, compile, and debug without ever leaving Turbo Pascal. And for big or complex programs that require the full range of debugging support from machine language to evaluating Pascal expressions, Turbo Pascal fully supports Borland's standalone debugger, Turbo Debugger.

Taxonomy of bugs

There are three basic types of program bugs: compile-time errors, run-time errors, and logic errors.
Compile-time errors

A compile-time, or syntax, error occurs when you violate a rule of Pascal syntax: leave out a semicolon, forget to declare a variable, pass the wrong number of parameters to a procedure, assign a real value to an integer variable. What it really means is that you're writing statements that don't follow the rules of Pascal.

Turbo Pascal won't compile your program (generate machine code) until all your syntax errors are gone. If Turbo Pascal finds a syntax error while it is compiling your program, it stops compiling, goes into your source code, locates the error, positions the cursor there, and displays an error message in the Edit window. Once you've corrected it, you can start compiling again.

If you're using the command-line version (TPC.EXE), Turbo Pascal will print out the offending statement, along with the line number and the error message. You can then go into whatever editor you're using, find the line, fix the problem, and recompile.

For more about error messages, refer to Appendix A in the Programmer's Guide.

Run-time errors

A run-time, or semantic, error happens when you compile a syntactically legal program that does something illegal when it executes, such as opening a nonexistent file for input or dividing by 0. In that case, Turbo Pascal halts your program and prints an error message to the screen that looks like this:

```
Run-time error ## at seg:ofs
```

If you're running in the IDE, Turbo Pascal automatically finds the location of the run-time error, pulling in the appropriate source file.

If you ran your program from the DOS prompt, you'll be returned to DOS. You can load TURBO.EXE and use Search | Find Error to locate the position in your source (make sure Destination is set to Disk). You can also use the command-line compiler (TPC.EXE) /F option to find the error.

Logic errors

Logic errors mean that your program does what you told it to do instead of what you want it to do. A variable may not have been initialized; calculations may turn out wrong; pictures drawn
onscreen don't look right; or the program might just skip doing what you think it should.

These can be the hardest errors to find, but they are the ones that the integrated debugger helps you with the most.

The integrated debugger

Some run-time and logic errors are obscure and hard to track down. Others can be buried by subtle interactions between sections of a large program. In these cases, what you'd really like to do is to execute your program interactively, watching the values of certain variables or expressions. You'd like your program to stop when it reaches a certain place so that you can see just how it got there. You'd like to stop and change the values of some variables while the program is executing, to force a certain behavior or see how the program responds. And you'd like to do this in a setting where you can quickly edit, recompile, and run your program again.

Turbo Pascal's integrated debugger has all the capabilities just described and more. It is an integral part of the Turbo Pascal IDE: Two of the main menu items (Run and Debug) are devoted to its use; likewise, several hot keys are used for debugger commands. For more about the IDE and hot keys, refer to Chapter 7, “The IDE reference,” or try TPTOUR or online help.

What the debugger can do

The integrated debugger performs in an uncomplicated manner. There are no special instructions in your code, no increase in the size of your .EXE file, and no need to recompile to create a standalone .EXE once you've finished debugging.

If your program is divided into a number of units, the source code for each is automatically loaded into the editor as you trace execution.

If you use overlays, the debugger handles them automatically within the IDE, smoothly switching back and forth between the compiler, the editor, and the debugger.
Here's an overview of the debugger's features:

### Tracing

**RunTrace Into** You can execute one line in your program, then pause to see the results. When procedures or functions within your program are called, you have the option of executing the call as a single step, or of tracing through that routine line by line.

You can also trace your program's output line by line. You can have it swap screens as needed, or use dual monitors. You can also bring up the output screen in a separate window.

### Go to cursor

**RunGo to Cursor** You can move the cursor to a specific line in your program, then tell the debugger to execute your program until it reaches that line. This makes it easy to skip over loops and other tedious sections of code; it also lets you go right to the spot where you want to start debugging.

### Breaking

**DebugBreakpoints** You can mark lines in your program as breakpoints. When you run your program and it comes to a breakpoint, it stops and displays the source code with the breakpoint in the execution bar. You can then examine variables, start tracing, or run the program until another breakpoint is encountered. You can attach a condition to a breakpoint. You can also break at any point during program execution by pressing Ctrl-Break. This has the effect of stopping at the next source line, as if a breakpoint had been set there.

### Watching

**DebugWatches** You can set up a number of watches in the Watch window. Each one can be a variable, data structure, or expression. The watches change to reflect their current values as you step through your program.

### Evaluate/Modify

**DebugEvaluate/Modify** You can bring up the Evaluate and Modify box, which lets you interactively examine the value of variables, data structures, and expressions. You can change the value of any variable, including strings, pointers, elements of an array, and fields of a record. This provides an easy mechanism for testing how your code reacts to certain sets of values or conditions.
Navigating

You can quickly locate procedure or function declarations, even if your program is broken up into many modules (Search | Find Procedure). During a trace, you can quickly scroll back through the procedure or function call(s) that led to where you are and examine the parameters for each call (Window | Call Stack).

In and out of the debugger

Before you start debugging, you should understand that the basic unit of execution in the debugger is a line, not a statement. More accurately, the smallest unit of execution is a line. If you have several Pascal statements on a single line, they will all be executed together with a single press of F7. If, on the other hand, you have a single statement spread out over several lines, then the entire statement will be executed by pressing F7 once. All the execution commands are based on lines, including single-stepping and breakpoints; the line about to be executed is always shown in the execution bar.

Before you start debugging a program, the compiler must be able to generate the necessary symbol table and line-number information for your programs. The debugging compiler directives $L+$ and $D+$ that do this are on by default; they correspond to the menu items Options | Compiler | Local Symbols and Options | Compiler | Debug Information, respectively. Also checked by default is the Options | Debugger | Integrated option, which generates debugging information in the executable file.

{$D+}$ generates line-number tables that map object code to source positions. {$L+$} generates local debug information, which means it creates a list of the identifiers local to each procedure or function, so that the debugger can "remember" them while you're debugging. When you use the compiler directives, separate them by a comma and no spaces, and precede only the first directive by a $; for example, {$D+,L+}.

When you step through your program, Turbo Pascal will sometimes swap to the User screen, execute your code, then swap back to the integrated environment to await your next command. You can control when this screen swap occurs with the Options | Debugger | Display Swapping setting, which has three possible values:
When the Smart option is on (it is by default), the IDE only swaps to the User screen when a program line accesses video RAM or when a subroutine is stepped over.

When the Always option is on, the User screen is swapped with each step.

When the None is on, no display swapping ever occurs, and the IDE remains visible at all times. If the program writes to the screen or if user input is required, the text will overwrite the IDE screen. You can have Turbo Pascal repaint its windows by choosing Refresh Display.

The quickest way to start debugging is to load in your program and choose Run | Trace Into (F7). Your program gets compiled, and when it's finished, the editor will display the main body of your program, with the execution bar on the initial begin. You can continue to trace from there (using F7 and F8), or you can use the other methods we describe here.

If you know where in the program you want to start debugging, you can have your program execute until it reaches that spot, then have it pause there. To do this, just bring up that section of code in the editor and move the cursor to the line where you want to stop. You can then do one of two things:

- You can choose Run | Go to Cursor (or press F4), which will execute your program until it reaches that point, then pause.
- You can set a breakpoint there (choose Debug | Toggle Breakpoint or press Ctrl-F9), and then run your program (choose Run | Run or press Ctrl-F9); it will now stop every time it reaches that line. You can set several breakpoints, in which case your program will stop whenever it comes to any of the breakpoints.

If you're in the middle of debugging a program and want to start all over again, choose the Program Reset command from the Run menu. This reinitializes the debugging system so the next step command will take you to the first line in the main body of your program. At the same time, it closes any files your program may have opened, clears the stack of any nested subroutine calls, and releases any heap space being used. It does not reinitialize or otherwise modify any variables (Turbo Pascal never initializes variables automatically); typed constants, however, are restored to their original values.
Turbo Pascal will also offer a restart if you make any changes to the program itself while debugging. For example, if you modify any part of the program, then press any execution command (F7, F8, F4, Ctrl-F9, and so on), you’ll get a box with the message “Source modified, rebuild? (Y/N).” If you press Y, Turbo Pascal will re-make your program and start debugging from the beginning. If you press N, Turbo Pascal assumes you know what you’re doing and continues the debug session in progress. (Any source code changes you made will not affect program execution until you recompile. If you added or deleted lines, the execution bar will not compensate for these changes and may appear to highlight the wrong line.)

Ending a debugging session
While you’re debugging a program, Turbo Pascal keeps track of where you are and what you’re doing. And since you can load and even edit different files while you’re debugging, Turbo Pascal does not interpret loading a different file into the editor as “ending” a debugging session. So, if you want to run or debug a different program, let Turbo Pascal know by choosing the Run! Program Reset command (Ctrl-F2).

Tracing through your program
The simplest debugging technique is single-step tracing, which traces into procedures and functions. Load the following program (RANGE.PAS) in Turbo Pascal:

```pascal
{$D+,L+}   { To be sure complete debug information is generated }
{$R-}      { To be sure range checking is off }
program RangeTest;
var
    List: array[1..10] of Integer;
    Indx: Integer;
begin
    for Indx := 1 to 10 do
        List[Indx] := Indx;
    Indx := 0;
    while (Indx < 11) do
        begin
            Indx := Indx + 1;
            if List[Indx] > 0 then
                List[Indx] := -List[Indx];
        end;
    for Indx := 1 to 10 do
        Writeln(List[Indx]);
end.
```

Chapter 5, Debugging Turbo Pascal programs
To start debugging, press F7. You’re asking Turbo Pascal to execute the first line in the main body of your program. Note that the execution bar is on the begin on line 7. Since you haven’t compiled your program yet, Turbo Pascal does it automatically, and then prepares to single-step your program.

Press F7 a few more times. The execution bar moves to List[Indx] := Indx;, and appears to stay there. What’s happening is that this line is executing in a loop.

Choose the Debug | Watches | Add Watch command (Ctrl-F7) to display the Add Watch box. You’re going to monitor the values within your program by setting a watch; a watch is a variable, data structure, or expression.

What appears in the Add Watch box depends on where your cursor is positioned when you press Ctrl-F7. If you position the cursor on the first letter of any alphanumeric string, within it, or immediately following it, the string will be copied to the Add Watch box and highlighted. So, if the cursor is positioned on Indx, Indx will appear in the box. To change what’s in the box, start typing and the original expression and the highlight will disappear.

Once the Add Watch box is displayed, regardless of its contents, you can add more to it by pressing the → key (which copies more text from the editor). Place List in the box by using the → and press Enter. A line like the following will appear in the Watch window at the bottom of your screen:

- List: (1,2,0,0,0,0,0,0,0,0)

Now, press Ctrl-F7 again and type Indx and press Enter. Indx is listed first in the Watch window, making it look something like this:

- Indx: 3
List: (1,2,0,0,0,0,0,0,0,0)

Now press F7 again, and you’ll see the values of Indx and List change in the Watch window, reflecting what’s happening in your program.

As you enter the while loop, you’ll again see the values of Indx and List change, step by step. Note that the change in the Watch window reflects the actions of each line after you press F7.

Keep pressing F7 until you’re at the top of the while loop, with Indx equal to 10. This time through the loop, press F7, slowly
watching how the values in the Watch window change. When you execute the statement

\[
\text{List}[\text{Indx}] := -\text{List}[\text{Indx}];
\]

the value of \textit{Indx} changes to \(-11\). If you continue to press \textit{F7}, you’ll find that what you have is an infinite loop.

This program will compile and run. And run. And run. It gets stuck in an infinite loop because the \textbf{while} loop executes 11 times, not 10, and the variable \textit{Indx} has a value of 11 the last time through the loop. Since the array \textit{List} only has 10 elements in it, \textit{List}[11] points to some memory location outside of \textit{List}. Because of the way variables are allocated, \textit{List}[11] happens to occupy the same space in memory as the variable \textit{Indx}. This means that when \textit{Indx} = 11, the statement

\[
\text{List}[\text{Indx}] := -\text{List}[\text{Indx}];
\]

is equivalent to

\[
\text{Indx} := -\text{Indx}
\]

Since \textit{Indx} equals 11, this statement sets \textit{Indx} to \(-11\), which starts the program through the loop again. That loop now changes additional bytes elsewhere, at the locations corresponding to \textit{List}[-11..0]. And because \textit{Indx} never ends the loop at a value greater than or equal to 11, the loop never ends.

The important point is that, in just a few minutes and using only two keystrokes (\textit{F7} and \textit{Ctrl-F7}), you quickly and easily tracked down a subtle, nasty bug.

---

\textbf{Stepping through your program}

Trace Into is one debugging technique; \textbf{Step Over (F8)} is yet another, one that "steps over" subroutine calls. Both \textbf{Step Over} and \textbf{Trace Into} have a special meaning at the \textbf{begin} statement of the main program if your program uses units with initialization code. In this case, F7 will step into each unit’s initialization code, allowing you to see how each one of your units is set up. F8 will step over the initialization code, leaving the execution bar on the next executable line after the \textbf{begin}.

Consider the following (incomplete) sample program:

\[
\{$D+,L+$
\]

\begin{verbatim}
program TestSort;
const
\end{verbatim}
NLMax = 100;

```pascal
type
  NumList = array[1..NLMax] of Integer;
var
  List: NumList;
  I,Count: Word;

procedure Sort(var L: NumList; C: Word);
begin
  { sort the list }
end; { of proc Sort }
```

```pascal
begin
  Randomize;
  Count := NLMax;
  for I := 1 to Count do
    List[I] := Random(1000);
  Sort(List,Count);
  for I := 1 to Count do
    Write(List[I]:8);
  Readln;
end. { of program TestSort }
```

Suppose you’re debugging the `Sort` procedure. You want to trace your call to `Sort`, including checking the values within `List` before calling it. However, it gets tedious stepping through that first `for` loop 100 times as it initializes `List`. There must be a way you can get the loop to execute without having to single-step each line.

In fact, there are a few ways. First, you could put it in a separate procedure and press `F8` when you get to it, but that’s a bit drastic. Second, you could set a breakpoint within your program, which is a place in your program where you want execution to run to, then stop at. Finally, you could move the cursor to the line calling `Sort` and choose the Run | Go to Cursor command (`F4`). Your program will execute until it gets to the line containing the cursor. The execution bar will move to that line; you can start tracing from there, in this case by pressing `F7` to trace into `Sort`.

`Run | Go to Cursor` (`F4`) works through multiple levels of subroutine calls, even if the source code is in another file. For example, you could place the cursor somewhere within `Sort` and press `F4`; the program would execute until it reached that line within `Sort`. For that matter, `Sort` could be in a separate unit, and the debugger would still know when to stop and what to display.

There are three cases where Go to Cursor (`F4`) will not run to the line containing the cursor.
Using breakpoints

You can have up to 16 breakpoints active at a time.

Breakpoints only exist during your debugging session; they aren't saved in your .EXE file if you compile your program to disk.

Note that you cannot see the breakpoint highlight when the execution bar is on the breakpoint line.

1. When you have the cursor positioned between two executable lines, for example, a blank line or a comment line within a code block, the program will run to the next line containing executable statements.

2. When you have the cursor positioned outside the scope of a procedure block, for example, on the program statement or variable declarations, The debugger will tell you there is "no code generated for this line."

3. When you position the cursor on a line that will never gain control; for example, the line above the execution bar (assuming you're not in a loop) or the else part of a conditional statement when the if expression is true, the debugger will behave as if you had chosen Run | Run (Ctrl-F9). Your program will run until it terminates or until a breakpoint occurs.

Let's say that you trace through Sort for a while, then want the program to finish executing so you can see the output. How would you do this? First, you would move the cursor to the final end statement in the main body of the program, then choose Run | Go to Cursor (F4). Or you could choose Run | Run (Ctrl-F9), which will tell the debugger to let your program continue normal execution. Your program will then run until it ends or hits a breakpoint that you've set, or until you press Ctrl-Break.

Breakpoints are an important part of debugging. They're like having a stop sign embedded in your program: When your program encounters one, it stops execution and waits for further debugging instructions.

To set a breakpoint, move the cursor to each line in your program where you want it to pause. Any line where a breakpoint is set should contain at least one executable statement. It should not be a blank line, a comment, or a compiler directive; a constant, type, label, or variable declaration; a program, unit, procedure, or function header. To set a line as a breakpoint, choose the Debug | Toggle Breakpoint command (Ctrl-F8), which highlights it.

Once you've set your breakpoints, execute your program by choosing Run | Run (or pressing Ctrl-F9). Your program executes normally until a breakpoint is encountered. Then the program halts, the appropriate source code file (main program, unit, or
Include file) is loaded in, and the Edit window is displayed with the execution bar on top of the breakpoint line. If any variables or expressions have been added to the Watch window, they are also displayed with their current values.

At this point, you can use any number of debugging options.

- You can step through your code using Run | Trace Into, Step Over, or Go to Cursor (F7, F8, or F4). You can examine and modify variables.
- You can add or remove expressions from the Watch window.
- You can set or clear breakpoints.
- You can view program output with Windows | User Screen (Alt-F5).
- You can re-start your program from the beginning (using Run | Program Reset and then a step command).
- You can continue execution to the next breakpoint (or to the end of the program) by choosing Run | Run (Ctrl-F9).

To clear a breakpoint from a line, move the cursor to the line and choose Debug | Toggle Breakpoint (Ctrl-F8) again. This command toggles the breakpoint line on and off; if you use it on a breakpoint line, that line returns to normal.

Let's go back to the earlier example:

```
begin { main body of TestSort }
    Randomize;
    Count := NLMax;
    for I := 1 to Count do
        List[I] := Random(1000);
    Sort(List,Count);
    for I := 1 to Count do
        Write(List[I]:8);
    Readln;
end. { of program TestSort }
```

The idea here was to skip over the initial loop and start tracing with the call to Sort. The new solution is to move the cursor to the line calling Sort and choose Debug | Toggle Breakpoint (Ctrl-F8), making it a breakpoint. Now, run to the breakpoint by choosing Run | Run (Ctrl-F9). When the program gets to that line, it will stop and allow you to begin debugging.
Using Ctrl-Break

In addition to any breakpoints you might set, you also have an “instant” breakpoint during execution: pressing Ctrl-Break. This means that, barring a major crash, you can interrupt your program at any time. When you press Ctrl-Break, you drop out of your program and back into the editor, with the execution bar on the next line and ready for single-stepping.

What actually happens is that the debugger hooks itself into DOS, the BIOS, and other services. In this way, it knows whether or not the code currently executing is a DOS routine, BIOS routine, or your program. When you press Ctrl-Break, the debugger waits until the program itself is executing. It then starts stepping every machine-level instruction until the next instruction is at the beginning of a Pascal source code line. At that point, it breaks, moves the execution bar to that line and prompts you to press Esc.

If a second Ctrl-Break is detected before the debugger locates and displays the source code line, then the debugger terminates the program and doesn’t try to find the source line. In such a case, the exit procedures are not executed, which means that files, video mode, and DOS memory allocations might not be completely cleaned up.

Watching values

Program flow tells you a lot, but not as much as you’d like. What you really want to do is watch how variables change as your program executes. Suppose the Sort procedure for the earlier program looked like this:

```pascal
procedure Sort(var L: NumList; C: Word);
var
  Top, Min, K: Word;
  Temp: Integer;
begin
  for Top := 1 to C-1 do
    begin
      Min := Top;
      for K := Top+1 to C do
        if L[K] < L[Min] then
          L[Min] := L[K];
      if Min <> Top then
        begin
          Temp := L[Top];
          L[Top] := L[Min];
```
There is a bug here, so step through it (using Run | Trace Into or F7) and watch the values of L, Top, Min, and K.

The debugger lets you set up watches to monitor values within your program as it executes. The current value of each watch is shown, updated as each line in the program executes.

Set up a watches for each identifier using Debug | Watch | Add Watch (Ctrl-F7) to add each expression to the Watch window. The result might look like this:

- K: 21341
- Min: 51
- Top: 21383
- L: (163,143,454,622,476,161,850,402,375,34)

This presumes you’ve just stepped into Sort and the execution bar is on the initial begin statement. (If you haven’t stepped into Sort yet, “Unknown Identifier” will be displayed next to each Watch expression until you do.) Note that K, Min, and Top just have random values, since they haven’t been initialized yet. The values in L are supposed to be random; they won’t look just like this when you run the program, but they will all be non-negative values from 0 to 999.

Pressing F7 four times will move you down to the line if L[K] < L[Min] then, where you’ll notice that K, Min, and Top now have values of 2, 1, and 1, respectively. Keep pressing F7 until you drop out of that inner for loop, through the if Min <> Top then line, back to the top of the outer loop, and down again to if L[K] < L[Min] then. At this point, the Watch window would look like this (given the previous values in L):

- K: 3
- Min: 2
- Top: 2
- L: (34,143,454,622,476,161,850,402,375,34)

By now, you may have noticed two things. First, the last value in L (34)—which also happens to be the lowest value—got copied into the first location in L, and the value that was there (163) has disappeared. Second, Min and Top were the same value all the way through. In fact, if you look closely, you’ll notice something else: Min gets assigned the value of Top, but is never changed anywhere else. Yet the test at the bottom of the loop is if Min <>
Top then. Either you have the wrong test, or there's something wacky between those two sections of code.

As it turns out, the bug is in the fifth line of code: It should read
\[
\text{Min} := k;
\]
instead of
\[
L[\text{Min}] := L[k].
\]
Correct it, move the cursor to the initial `begin` in `Sort`, and choose `Run | Go to Cursor (F4)`. Since you've changed the program, a box will appear with the question “Source modified, rebuild? (Y/N)”; press `Y`. Your program will recompile, start running, then pause at the initial `begin` in `Sort`. This time, the code works correctly: Instead of overwriting the first location with the lowest value, it swaps values, moving the value in the first location to the position where the lowest value was previously. It then repeats the process with the second location, the third, and so on, until the list is completely sorted.

### Types of watch expressions

You can put any kind of constant, variable, or data structure in the Watch window as an expression; you can also put in Pascal expressions. Specifically, here are the expressions you can add and how each will be displayed:

<table>
<thead>
<tr>
<th>Expression</th>
<th>Display</th>
</tr>
</thead>
<tbody>
<tr>
<td>Integers</td>
<td>Decimal and hex. Examples: –23, $10</td>
</tr>
<tr>
<td>Reals</td>
<td>Without an exponent, if possible. Examples: 38328.27, 6.283e23</td>
</tr>
<tr>
<td>Characters</td>
<td>Printable: in single quotes (including extended graphics characters) as themselves. Control characters: as ASCII codes or printable. Examples: ‘b’, ‘Ø’ #4</td>
</tr>
<tr>
<td>Booleans</td>
<td>True or False</td>
</tr>
<tr>
<td>Enumerated data values</td>
<td>Actual named values (all uppercase). Examples: RED, JAN, WEDNESDAY</td>
</tr>
<tr>
<td>Pointers</td>
<td><code>segment:offset</code> hex format. Examples: PTR($3632,$106), PTR(CSEG,$220)</td>
</tr>
<tr>
<td>Strings</td>
<td>In single quotes. Examples: ‘Bruce’</td>

<td>Records</td>
<td>In parentheses, fields separated by commas. Nested records as nested lists. Examples: (5,10,‘Borland’,RED,TRUE)</td>
</tr>
<tr>
<td>Objects</td>
<td>Same as record. Expressions valid for records are also valid for objects.</td>
</tr>
<tr>
<td>Sets</td>
<td>In brackets, with expressions separated by commas; subranges are used when possible. Examples: [MON,WED,FRI] [‘0’..‘9’,‘A’..‘F’]</td>
</tr>
<tr>
<td>Files</td>
<td>In <code>(status,name)</code>, where <code>status</code> is CLOSED, OPEN, INPUT, or OUTPUT, and <code>name</code> is name of disk file assigned to file variable. Examples: (OPEN,’BUDGET.DTA’)</td>

Chapter 5, Debugging Turbo Pascal programs 135
Format specifiers

To control exactly how information is displayed in the Watch window, Turbo Pascal allows you to add format specifiers to your Watch expressions. A format specifier follows the Watch expression, separated from it by a single comma. (You don't need format specifiers to debug; this is an advanced topic.)

A format specifier consists of an optional repeat count (an integer), followed by zero or more format characters; no spaces are required between the repeat count and the format characters. The repeat count is used to display consecutive variables, such as the elements of an array. For example, assuming List is an array of 10 integers, the Watch expression List would display:

List: (10,20,30,40,50,60,70,80,90,100)

If you want to look at a particular range of the array, you can specify the index of the first element, and add a repeat count:

List[6],3: 60,70,80

This technique is particularly useful for dealing with arrays that are too large to be displayed completely on a single line.

Repeat counts aren't limited to arrays; any variable may be followed by a repeat count. The general syntax var, x simply displays x consecutive variables of the same type as var, starting at the address of var. Note however, that the repeat count is ignored if the Watch expression does not denote a variable. A good rule of thumb is that a given construct is a variable if it can legally appear on the left-hand side of an assignment statement, or be used as a var parameter to a procedure or function.

To demonstrate the use of format specifiers, assume that the following types and variables have been declared:

\begin{verbatim}
type
  NamePtr = 'NameRec;
  NameRec = record
    Next: NamePtr;
    Count: Integer;
    Name: string[31];
  end;
var
  List: array[1..10] of Integer;
  P: NamePtr;
\end{verbatim}

Given these declarations, the following Watch expressions can be constructed:
Typecasting

Typecasting is another powerful feature you can use to modify how Watch expressions are displayed, letting you interpret data as a different type than it would normally be. This can be especially useful if you’re working with an address or a generic pointer, and you want to view it as pointing to a particular data type.

Suppose your program has a variable `DFile` that is of type `file of MyRec`, and you execute the following sequence of code:

```pascal
Assign(OFile,'INPUT.REC');
Reset(OFile);
```

If you add `DFile` as a watch, the corresponding line in the Watch window will look like this:

```
DFile: (OPEN.'INPUT.REC')
```

But you might want more information about the file record itself. If you change your program so that it uses the `Dos` unit, then you can modify the `DFile` watch to `FileRec(DFile),rh`, which means, “Display `DFile` as if it were a record of type `FileRec` (declared in the `Dos` unit), with all record fields labeled and all integer values displayed in hexadecimal.” The result in the Watch window might look something like this:

```
FileRec(DFile),rh: (HANDLE:$6;MODE:$D7B3;RECSIZE:$14;PRIVATE:($0,$0,...))
```

The record is too large to view at once; however, you can use the cursor movement keys to scroll the data not visible on the screen (see the section “Editing and deleting watches” on page 139).

With this typecasting, you can now watch specific fields of `DFile`. For example, you could view the `UserData` field by adding the expression `FileRec(DFile).UserData` to the Watch window:

```
FileRec(DFile).UserData: (0,0,0,0,0,0,0,0,0,0,0,0,0,0,0)
```

You can apply the same technique to data structures and types of your own design. If they’re declared in your program or units, you can typecast to them in the Watch window. The rules for typecasting are explained in Chapter 6 of the *Programmer’s Guide, Expressions.*
Expressions  As we mentioned earlier, you can use expressions as Watch expressions; you could have calculations, comparisons, address offsets, and other such expressions. Table 5.1 lists the kinds of features legal in a Watch expression, as well as acceptable values.

Table 5.1: Watch expression values

In other words, the expression must be a normal, legal Pascal expression, and can use any or all of the features described in
Editing and deleting watches

You can't change the value of the expression, only the expression itself. To change the value, use Debug | Edit Watch.

Evaluating and modifying

The Watch window is wonderful for tracing values as you step through your program. Other times, you may want to interactively check a variable or change its value without creating a watch point.

To accommodate these needs, the debugger offers the Evaluate and Modify window. To bring it up, choose the Debug | Evaluate/Modify command (or press Ctrl-F4). This window contains the Expression, Result, and New value boxes.

As with the Add watch box, the Evaluate and Modify box already contains the word found at the cursor; it’s in highlight mode. Edit it as you would the Add Watch box and press Enter when you want to evaluate it. The current value of the constant, variable, or expression will then appear in the Result box.

The Evaluate box accepts exactly the same set of constants, variables, and expressions that the Watch window does. You have the same freedoms and restrictions we've already mentioned. You can also use the same format characters as you can for Watch expressions.

Table 5.1. See “Modification issues” on page 140 for information on how to modify Watch expressions.

It's easy to edit, add, or delete watches. When the Watch window is active, the currently active expression is highlighted. To select a different expression, use the Home, End, ↑, or ↓ keys.

To edit (change) the currently highlighted watch, you can choose Debug | Watches | Edit Watch. Even easier, as shown on the bottom line of the screen, you can press Enter. The debugger opens a pop-up window with the selected expression, and you can edit it. You already know how to add watches, but once the Watch window is active, there's an easier way: Press Ins. A pop-up window appears. You can type in the watch expression, add to it with the → key, or accept the default that was copied from the cursor position.

To delete the current watch, choose Debug | Watches | Delete Watch, or simply press Del. You can delete all of the watches by choosing Debug | Watches | Remove All Watches.
When you press Enter, the identifier or expression in the Evaluate box is highlighted again, which means if you start typing a new name (without pressing Ins or an arrow key), it will replace the old one. This lets you quickly type in a series of variables and expressions.

The New Value box allows you to modify the value of the variables named in the Evaluate box. You can enter a constant value, the name of another variable, or even an expression. The resulting value must be of a type compatible with the variable in the Evaluate box. Therefore, if you have an expression in Evaluate that does not result in a memory location, then any value entered in New Value will result in the message “Cannot be modified.”

The Result box shows the current value of whatever is in the Evaluate box, using the same format as the Watch window. And, like the Watch window, the data will sometimes be too large to fit. In such cases, you can use the Tab, Backtab, ←, →, Home, and End keys to scroll through the box.

In all cases, you can use the ↑ and ↓ keys (or regular keyboard editing commands) to move between the three boxes. Once you have modified a box, press Enter to evaluate the input.

Modifying expressions

The ability to modify a variable while the program is running is a tremendous help while debugging. It can also be dangerous, so you need to be sure you know the do’s and don’ts of modification.

The simplest form of modification is to enter a variable name in the Evaluate box and a corresponding value in the New Value box. When you press Enter after typing in the new value, the variable’s value is changed, and the Result box is updated to reflect that.

You are not limited to constant values, though. You can enter into the New Value box any variable or expression that you could enter into the Evaluate box, with one major qualification: It must be assignment-compatible with the variable or expression in the Evaluate box. In other words, if expr1 represents what’s currently in the Evaluate box, then you cannot legally enter the expression expr2 into the New Value box if the statement

\[ expr1 := expr2; \]

would cause a compiler or run-time error.
Note that the reverse is not necessarily true: There are cases when
the statement

\[ expr1 := expr2; \]

is legal, but you still cannot use \( expr2 \) in the New Value box.

If the expression entered is an incompatible type—such as
entering a floating-point value for an integer variable—then the
Result box will instead display the message "Type mismatch." To
make the Result box redisplay the current value of the variable,
move back up to the Evaluate box and press \textit{Enter}.

If the expression entered yields an out-of-range value—such as
entering 50,000 for a variable of type Integer—the Result box will
display the message "Constant out of range." The same thing will
occur if you type in an array element with an index that's out of
range.

If the expression entered in the New Value box is one that can’t be
assigned, then the Result box will get the message "Cannot
evaluate this expression." Such expressions include arrays,
records, sets, and files.

Likewise, if the variable or expression in the Evaluate box is one
that can’t be modified—a whole array, record, set, or a file—then
attempting to assign a value to it will produce the message
"Cannot be modified."

What can you modify? Refer to Table 5.1 on page 138 for a list of
what can be used in a Watch expression, along with acceptable
values. Remember, though, that expressions can only use the
built-in functions listed as acceptable for Watch expressions in
Table 5.1.

Other things to keep in mind:

- You can’t modify entire arrays, entire records, or files; however,
  as mentioned, you can modify individual elements of arrays or
  records that resolve to one of the types listed in Table 5.1,
  provided they are not themselves arrays or records.
- You can’t directly modify untyped parameters passed into a
  procedure or function. You can, however, typecast them to a
given type, then modify them according to the restrictions
we’ve just detailed.
- Be aware that there can be some real dangers in modifying
  variables. For example, if you change a pointer, you could end
up making changes to memory that you didn’t mean to, possibly even modifying other variables and data structures.

Navigation

When you are debugging a large program, especially one spread out over several units, you can actually get lost, or at least buried so deep that you can’t figure out how best to get to where you want to go. To aid you with navigation, the debugger provides two mechanisms: the Window | Call Stack and Search | Find Procedure commands.

The call stack

Each time a procedure or function is called, Turbo Pascal remembers the call and the parameters passed to it by pushing the information on the call stack. When you exit that procedure or function, then the call is popped off the stack, returning execution to the calling routine.

Whenever your program pauses because of a breakpoint or a single-step command, you can ask to see the current call stack by using the Window | Call Stack command (Ctrl-F3). This displays a window that shows the list of procedure/function calls currently active on the stack.

The call stack allows you to look back through the sequence of calls. When you first bring up the call stack, the topmost call is highlighted. You can use the arrow keys to move up and down through the stack. If you press Spacebar, you will be taken to the last active point within that program. Consider the following small program (TESTPOWER.PAS):

```pascal
program TestPower;

function Power(Base, Exp: Word): Longint;
begin
  if Exp <= 0 then
    Power := 1
  else
    Power := Base * Power(Base, Exp-1);
end; { of func Power }

begin { main body of TestPower }
  Writeln('2 A 14 = ', Power(2, 14));
end. { of program TestPower }
```

A CGA will display 9 calls; a Hercules, EGA, or VGA will display 12.

Compile TESTPOWER, and set a breakpoint on the second line of the function Power (the line Power := 1). Now run the program.
Finding procedures and functions

Sometimes, in the middle of debugging, you want to find a particular procedure or function in order to set a breakpoint, execute to that point, check the parameter list, look at the variables, or any number of other reasons.

If your source code is spread out among multiple files, you’ll love the Search | Find Procedure command. This command leads you to a small window, where you can enter the name of a procedure or function. After you type in an identifier and press Enter, Turbo Pascal checks its internal tables to find where that subprogram is located, loads in the appropriate source file (if necessary), and puts you in the Edit window with the cursor positioned at the beginning of the procedure or function.

There are three important things to remember about using the Search | Find Procedure command:

- **Find Procedure does not affect your current debugging state.** In other words, if you’re paused at some point in your program, you are still paused there, and choosing Run | Trace Into (F7) will execute that line in your program, not the procedure or function you’ve just located.

- **Find Procedure places the cursor at the first executable line of that procedure or function, rather than on the procedure or function header.** This means you can choose Run | Go to Cursor (F4) to execute from your current position to the start of that procedure or function.

- **You can only use this command if you have compiled your program and debug information is available for the procedure or function.**

Since you may have routines with the same name in several different places in your program (in units, nested inside of other routines, and so on), it’s a good idea to qualify the routine’s name by preceding it with the name of the unit or program containing it, as well as any procedures or functions that might enclose it; for example, `module.proc.proc.<etc.>.proc`. If you modify the source code and the file position (or even name) of a procedure or function is changed, the Search | Find Procedure command won’t know about any of those changes until you recompile. If you first compile program `TestPower` (see the section on “The call stack,”...
page 142) and then delete the blank line above the declaration of function `Power`, `Search` | Find Procedure will put the cursor on the if...then instead of the begin.

Object-oriented debugging

You don't need to make any special preparations to debug an object-oriented program.

Working with objects in the IDE involves two functional areas: stepping and tracing through method calls, and examining object data. The integrated debugger "understands" objects and handles them automatically in a fashion consistent with related language components like procedures and records.

Stepping and tracing method calls

A method call is treated by the IDE as an ordinary procedure or function call. F8 (Step Over) treats a method call as an indivisible unit, and executes it without displaying the method's internal code; whereas F7 (Trace Into) loads the method's code if it's available, and traces through the method's statements.

There is no difference between tracing static method calls and tracing virtual method calls. Virtual method calls are resolved at run time, but because debugging happens at run time, there is no ambiguity, and the integrated debugger always knows the correct method to execute next.

The Call Stack window displays the names of methods prefixed by the object type that defines the method (for example, Circle.Init rather than simply Init).

Objects in the Evaluate window

When objects are displayed in the Evaluate and Modify window, they appear in a fashion very similar to records. All the same format specifiers apply, and all expressions that would be valid for records are valid for objects.

Only the data fields are displayed when the object name as a whole is presented to Evaluate. However, when the specific method name is evaluated, as in

ACircle.MoveTo
a pointer value is displayed indicating the address of the method’s code. This is true for both static and virtual methods. The integrated debugger handles virtual method lookup transparently through the virtual method table (VMT), and the address of a virtual method for a given object instance is the true address of the correct method code for that instance.

When it is tracing inside a method, the IDE “knows” about the scope and presence of the Self parameter. You can evaluate or watch Self, and you can follow it with format specifiers and field or method qualifiers.

Turbo Pascal allows the entry of expressions at the prompt for the Find Procedure command of the Search menu. To be legal, an expression must evaluate to an address in the code segment. Note that this applies to procedural variables and parameters as well as to object methods.

You’ve learned how to use the debugger; now we’ll cover some other issues that might arise while you’re debugging.

There are some simple things you can do to make your programs easier to debug. In most cases, don’t put more than a single statement on a line. Since the debugger executes on a line-by-line basis, this ensures that no more than one statement will be executed each time you press F7.

At the same time, recognize that there are cases when you might want to put multiple statements per line. If there is a list of statements you have to step through, but which aren’t really relevant to the debugging, feel free to bunch them up into one or two statements so that you can step through them more quickly. That’s why in one of the earlier examples we wrote

\[ W := 10; X := 20; Y := 30; Z := 40; \]

instead of

\[ W := 10; \]
\[
X := 20;
Y := 30;
Z := 40;
\]

You can also organize your variable declarations so that the ones you are most likely to put in the Watch window are nearest the initial begin statement of the procedure or function. When you step into that procedure or function, you can quickly move the cursor through the list, using Add Watch (Ctrl-F7) to add each variable as a watch.

In a similar fashion, if there are expressions that you commonly want to watch or evaluate at certain points in your program, insert them as comments. When you get to that point, you can move the cursor to the start of the expression and copy it into the Add Watch or Evaluate and Modify box. This is especially helpful if the expression is a complex one, involving typecasting, format characters, array elements, or record fields.

Finally, the best debugging is preventive debugging. A well-designed, clearly-written program will not only have fewer bugs, but it will make it easier for you to track down and fix what few bugs there are. Here are some basics to remember when you’re writing your program:

- Program incrementally. When possible, code, test, and debug your program one (small) section at a time. Get each section working before moving on to the next section.
- Break your program into modules: units, procedures, functions. Avoid writing procedures or functions longer than about 25 lines; if one gets bigger than that, try breaking it up into a few smaller procedures and functions.
- When possible, pass information through parameters only, instead of referencing global variables inside procedures and functions. This avoids side effects and also makes the code easier to debug, since you can easily watch all information coming in and out of a given procedure or function.
- Concentrate on making your program work correctly before trying to make it fast.

Memory issues

It is possible to run out of memory while debugging a large program. After all, Turbo Pascal is holding the editor, compiler, debugger, current source code file, executable code, symbol tables,
Changes you make in the Startup Options dialog box (Options | Environment) are permanent and saved directly into TURBO.EXE. Changes made to other dialog settings can be saved in a TURBO.TP configuration file. Refer to Chapter 7.

Outside the IDE

- Remove TSRs from memory. If you have Sidekick or Superkey loaded in memory or EMS, exit the IDE, remove them, and then reload TURBO.EXE.
- Modify CONFIG.SYS to remove unnecessary drivers (ANSI.SYS, disk caches, etc.). You can also reduce the number of files and buffers with FILES = 20, BUFFERS = 20. Make sure these changes are safe for any other software you are using.

Re-configuring Turbo Pascal

There are command-line parameters that you can pass to TURBO.EXE at startup that correspond to all the settings on the Options | Environment | Startup dialog box; refer to page 174.

If you have EMS available, disabling this option will have no effect on IDE capacity.

and any other debugging information in memory—all at the same time. You can monitor the amount of free memory with the File | Get Info command.

Both the IDE and Turbo Pascal itself are very configurable and there are several steps you can take to make more workspace available for compiling and debugging your programs. Some solutions are easy to implement, while others involve altering your code or turning off debug information selectively. Always start with the options that are painless and safe and then, if necessary, take progressively more radical steps in order to increase the IDE’s capacity. Once you find a system configuration that provides you with enough capacity, you might want to permanently modify the your AUTOEXEC.BAT, CONFIG.SYS, TURBO.TP, and TURBO.EXE files.

1. Set Compile | Destination to Disk.
2. On the Options | Linker dialog box, set Link Buffer to Disk.
3. Using the Options | Environment | Startup Options dialog box, try one or more of the following:

a. If you have expanded memory on your system (EMS), make sure the Use Expanded Memory option is enabled and make plenty of EMS available to Turbo Pascal (by reducing the amount of EMS being used by resident programs or drivers like RAM disks, Sidekick, etc.). The IDE can use at least 400K of EMS for overlays, extra buffers, and other system resources. All these will increase the workspace for your programs. (Making more than 400K EMS available will increase the IDE’s performance, although it will not make more memory available to compile and debug your programs.)

b. If you’re not trying to debug a graphics program, make sure the Graphics Screen Save option is disabled. Like all
If you don’t have the IDE load TURBO.TPL, you won’t be able to evaluate expressions using the Evaluate/Modify dialog box unless a debugging session is active.

Make sure to leave the extracted units on disk and in your unit (Options I Directories I Unit directories) so your programs can make use of the Dos, Crt, Overlay, and Printer units.

Of course, if you’re not debugging, you can greatly increase IDE capacity by disabling the Integrated switch (Options I Debugger).

startup options, you can enable this option on the command-line when you debug a graphics program.

c. Reduce the default of the Overlay and Window Heap Size options. Every kilobyte you subtract here yields another kilobyte for your program. If you have EMS available, reducing these heap sizes somewhat won’t have much negative impact on the IDE’s performance.

d. Disable the Load TURBO.TPL option. TURBO.TPL contains the commonly used standard units and is loaded into memory at startup to optimize linker performance. By disabling this option, you’ll still be able to compile and debug programs, but you’ll have to extract all the units from TURBO.TPL first (using the TPUMOVER utility; refer to UTILS.DOC on your distribution disk).

As an alternative, you can leave the Load TURBO.TPL option enabled and still reduce the size of TURBO.TPL by about 15K. Just extract all units from TURBO.TPL with the exception of SYSTEM.TPU. Then delete all units from TURBO.TPL with the exception of SYSTEM.TPU.

e. On a unit-by-unit basis, turn off debug information in those units that are already debugged. A common technique is to build a “test harness” around your code as you develop it. Once that code is implemented, tested and debugged, turn off symbol information in that unit by disabling the Debug Information switch (Options I Compiler dialog box) and recompiling. You can also imbed a {$D-} in the unit itself. If you do so, it’s a good idea to use conditional directives and defines to control enabling and disabling debug information in various units (refer to Chapter 21 in the Programmer’s Guide). If you proceed as described here and end up with debug information disabled everywhere in your program—and are still having capacity problems—consider modifying your code as described next.

Modifying your source code Some of the following measures are easy to do and yield big capacity gains. Others are more radical and you might want to use conditional directives (see Chapter 21 in the Programmer’s Guide) to turn them on or off.
- Overlay units in your program. This is very safe, flexible, and can dramatically increase the IDE workspace. Refer to Chapter 13 in the *Programmer’s Guide* for more information.

- Using the **Options | Memory Sizes** dialog box, reduce the **Stack Size** and **Low Heap Limit**. Make sure there’s enough stack for your program, especially if you’ve turned off stack checking as recommended next.

- Using the settings in the **Compiler Options** dialog box, try one or more of the following:
  
  - **Disable Range Checking** and **Stack Checking**. Stack Checking is on by default. Turn it off once your program is stable and you’ve determined its stack requirements.
  
  - **Disable Emulation** during debugging. Of course, only enable **Emulation** and **8087/80287 code generation** if you are doing IEEE floating point. If you have a numeric coprocessor on your debugging machine, disable **Emulation** while you’re debugging non-floating point code.

- Reduce the number of symbols in the interface sections of units. Don’t declare something in the interface section of a unit unless it’s used by code outside the unit. Doing this is good, safe programming practice and will make more symbol space available during the compilation of large programs.

Turbo Debugger and the IDE

Turbo Pascal itself and the IDE both offer many ways for you to gain capacity by making adjustments to default settings. If you run out of memory compiling or debugging your programs and have tried most of the painless ideas offered here, consider using the IDE to edit and compile your programs, and then using Turbo Debugger to debug them. If you have Turbo Debugger and want to use it to debug programs developed in the IDE, configure the IDE as follows:

1. Set **Compile | Destination** to **Disk**.
2. In the **Options | Debugger** dialog box, disable **Integrated** and enable **Standalone** debugging.

You can also use the command-line compiler, TPC.EXE, or the extended memory command-line compiler, TPCX.EXE to build massive programs (several megabytes in size). Then you can use TD, TD286 or TD386 to debug them.
Recursive routines

Recursion is a programming technique where a procedure calls itself (directly or indirectly). For example, the function Power shown in an earlier example is recursive, because it calls itself to calculate the value it needs to return.

There are some considerations to keep in mind when debugging recursive code. First, deep levels of recursion can eat up lots of system stack space, which can have other side effects (such as your program halting or crashing due to stack overflow). This is a general danger of using recursion under any circumstance; just be aware that, if your program crashes while debugging, it may well be due to stack overflow rather than anything you did with the debugger.

Also, if you have deep levels of recursion, you may not be able to find your way out immediately with the call stack. That’s because the call stack is limited to the last 128 function/procedure calls. You can, however, go to the bottom of the stack, use it to find the oldest call, pop out to that spot, then use the call stack again.

Each time a function is called recursively, it creates a new set of local variables and pass-by-value (non-var) parameters. If you have added these to the Watch window, be aware that these values will “float” to reflect the currently active local data.

Where debugging won’t go

There are some cases where you can’t trace into a given function or procedure. This is usually—but not always—because the source isn’t available. These situations include the following:

■ Any inline procedure or function; that is, any procedure or function of type inline. That’s because these aren’t procedure or function calls at all; the associated machine language is inserted in place of the “call.” Such a call is treated as a single statement.

Note that you can trace into procedures and functions that happen to use inline statements. However, in that case, each inline statement is treated as a single line, no matter how many lines it occupies. This follows the same rule as other statements; that is, if a single statement takes up several lines, it is treated by Run I Trace Into and Step Over (F7 and F8) as a single line.
Common pitfalls

There are a few problems that you often run into while debugging. Here's a list of things to watch out for:

- Not generating the global and local debug information needed. By default, both of these switches are on. If you have problems stepping into a program or unit, put \$D+,L+\ at the start of every program or unit you wish to debug.

- Starting to debug another program without clearing the breakpoints and Watch expressions from the previous one. Before loading in a new program to debug, you should always execute the following commands: Run | Program Reset (Ctrl-F2) Debug | Watches | Remove All Watches.

- Trying to compile and run another program when the previous one is still set up as the main file. Use the Compile | Main File command to clear out the previous name or set a new one.

- Press \texttt{N} when you get the “Source modified, rebuild? (Y/N)” prompt. This means that you’ve modified a source file while debugging, and the debugger’s line-number tables may no longer be valid. This can throw off breakpoints, stepping, and

- Any Turbo Pascal routine from one of the standard units (\texttt{Crt, Dos, Graph, Graph3, Overlay, Printer, System, Turbo3}).

- Any external procedure or function.

- Any interrupt procedure or function.

- Any procedure, function, or initialization code contained in a unit that was not compiled with the \$D+\ directive (or with Options | Compiler | Debug Information turned on).

- Any procedure, function, or initialization code contained in a unit whose source code cannot be found. If it’s not in the current or the unit directory, or if its source code is in a file named something other than \texttt{unitname.PAS} (where \texttt{unitname} is the name of the unit as given in the uses clause), the IDE will prompt you for the correct file name. If you enter a null file name, or if you press \texttt{Esc}, the debugger will move on as if debug information were not available.

- Any procedure set up as an exit procedure. If you step through your program with Run | Trace Into (F7), you’ll never step into an Exit procedure. Note, however, that you can set a breakpoint in an Exit procedure, and the debugger will break appropriately when the execution bar arrives at your breakpoint.
other debugging activities. If you just accidentally typed a character and then deleted it, you’re probably safe in pressing N; if you’ve inserted or deleted lines, though, you’re better off pressing Y, because the machine code you’re debugging doesn’t match the source code you’re looking at.

Error handling

In addition to the integrated debugger, Turbo Pascal provides several compiler directives and language features to help you trap programming errors. This section briefly describes some of those features.

You can insert run-time error checking for yourself by disabling the generation of automatic error-checking code and writing your own error-handling routines. Let’s take a look at some examples.

Input/output error checking

If you ran this program, entered the values 45 and 8x when prompted, and then pressed Enter, what would happen?

```pascal
program DoSum;
var
  A,B,Sum: Integer;
begin
  Write('Enter two numbers: '); Readln(A,B);
  Sum := A + B;
  Writeln('The sum is ',Sum);
end.
```

You’d get a run-time error (106, in fact) and the cursor would be positioned at the statement

```pascal
Readln(A,B);
```

What happened? The program expected an integer value and you entered non-numeric data—8x—which generated a run-time error.

In a short program like this, such an error isn’t a big bother. But what if you were entering a long list of numbers and had gotten through most of the list before making this mistake? You’d be
forced to start all over again. Worse yet, what if you wrote the program for someone else to use, and they slipped up?

Turbo Pascal allows you to disable automatic I/O error checking and test such errors for yourself within the program. To turn off I/O error checking at some point in your program, include the compiler directive \texttt{${I-}$} in your program (or the Options | Compiler | I/O Checking option). This instructs the compiler to prohibit the production of code that checks for I/O errors.

Range checking

Another common class of run-time errors involves out-of-range or out-of-bounds values. Some examples of how these can occur include assigning too large a value to an integer variable or trying to index an array beyond its bounds. If you want it to, Turbo Pascal will generate code to check for range errors. It makes your program slightly larger and slower, but it can be invaluable in tracking down any range errors in your program.

Let's revisit an earlier example:

\begin{verbatim}
program RangeTest;
var
  List: array[1..10] of Integer;
  Indx: Integer;
begin
  for Indx := 1 to 10 do
    List[Indx] := Indx;
  Indx := 0;
  while (Indx < 11) do
    begin
      Indx := Indx + 1;
      if List[Indx] > 0 then
        List[Indx] := -List[Indx];
    end;
  for Indx := 1 to 10 do
    Writeln(List[Indx]);
end.
\end{verbatim}

We discovered earlier that if you compile and run this program, it will get stuck in an infinite loop. This is caused by the \texttt{while} loop executing 11 times, not 10, and the variable \texttt{Indx} having a value of 11 the last time through the loop.
The Range Checking option is in the Options Compile dialog box. Range checking is off by default; turning range checking on makes your program slightly larger and slower, but is strongly advised until your program is thoroughly debugged.

How do you check for things like this? You can insert {SR+} at the start of the program to turn range checking on. Now, when you run it, the program will halt with run-time error 201 (out-of-range error, because the array index is out of bounds) as soon as you hit the statement if List[Indx] > 0 with Indx = 11. If you were running in the IDE, it would automatically take you to that statement and display the error.

There are some situations—usually in advanced programming—in which you may need to violate range bounds, most notably when working with dynamically allocated arrays or when using Succ and Pred with enumerated data types.

You can selectively implement range checking by placing the {SR-} directive at the start of your program. For each section of code that needs range checking, place the {SR+} directive at the start of it, and the {SR-} directive at the end. For example, you could have written the preceding loop like this:

```pascal
while Indx < 11 do
begin
  Indx := Indx + 1;
  {SR+}  
  if List[Indx] > 0 then
    List[Indx] := -List[Indx];
  {SR-}  
  end;
```

Range checking will be performed only in the if..then statement and nowhere else, unless, of course, you have other {SR+} directives elsewhere.

Other error-handling abilities

Turbo Pascal gives you the ability to perform other error-handling techniques, but because those techniques are described more fully in other parts of this manual, we’ll only touch on them briefly in this section.

When your program terminates, either normally or through a run-time error, a standard exit procedure is called that's linked in with your program. Turbo Pascal lets you add in your own exit procedures, which are called before the standard exit procedure. In fact, each unit can have its own exit procedure, so that you can have automatic cleanup code, as well as the usual automatic
initialization code. Exit procedures are described in more detail in Chapter 18 of the *Programmer's Guide*, "Control issues."

If you try to allocate memory (through a call to *New* or *GetMem*) and there isn’t sufficient memory on the heap, a heap error procedure is automatically called, which simply causes your program to exit with a run-time error. You can, however, install your own heap error procedure to handle things as you wish, like deallocating dynamic structures no longer needed or simply causing *New* or *GetMem* to return a nil pointer. Heap error procedures are described in more detail in Chapter 16 of the *Programmer's Guide*, "Memory issues."

If you’re using the *Graph* unit, you can perform error checking much as you do for I/O error checking. One function in the unit, *GraphError*, returns an error result set by many of the graphics routines. Chapter 12 of the *Programmer's Guide*, "The Graph unit and the BGI," provides you with details on how to use this and the error codes that are generated.

The *Overlay* unit contains an integer variable, *OvrResult*, that stores the result code from the last operation performed by the overlay manager. Similarly, the *Dos* unit stores its result codes in the variable *DosError*.

Project management

So far, you’ve learned how to write Turbo Pascal programs, how to use the predefined units, and how to write your own units. At this point, your program could become large, perhaps separated into multiple source files. How do you manage such a program?

This chapter suggests how to organize your program into units, how to take advantage of the built-in Make and Build options, how to use the stand-alone Make utility, how to use conditional compilation within a source code file, and how to optimize your code for speed.

Program organization

Turbo Pascal 6.0 allows you to divide your program into code segments. Your main program is a single code segment, which means that after compilation, it can have no more than 64K of machine code. However, you can exceed this limit by breaking your program up into units. Each unit can also contain up to 64K of machine code when compiled. The question is: How should you organize your program into units?

The first step is to collect all your global definitions—constants, data types, and variables—into a single unit; let’s call it MyGlobals. This is necessary if your other units reference those definitions. Unlike include files, units can’t “see” any definitions made in your main program; they can only see what’s in the interface.
section of their own unit and other units they use. Your units can use *MyGlobals* and thus reference all your global declarations.

A second possible unit is *MyUtils*. In this unit you could collect all the utility routines used by the rest of your program. These would have to be routines that don't depend on any others (except possibly other routines in *MyUtils*).

Beyond that, you should collect procedures and functions into logical groups. In each group, you'll often find a few procedures and functions that are called by the rest of the program, and then several (or many) procedures/functions that are called by those few. A group like that makes a wonderful unit. Here's how to convert it:

1. Copy all those procedures and functions into a separate file and delete them from your main program.
2. Open that file for editing.
3. Type the following lines in front of those procedures and functions:
   
   ```
   unit unitname;
   interface
   uses MyGlobals;
   implementation
   ```

   where *unitname* is the name of your unit (and also the name of the file you're editing).
4. Type *end.* at the very end of the file.
5. In the space between *interface* and *implementation*, copy the procedure and function headers of those routines called by the rest of the program. Those headers are simply the first line of each routine, the one that starts with *procedure* (or *function*).
6. If this unit needs to use any others, type their names (separated by commas) between *MyGlobals* and the semicolon in the *uses* statement.
7. Compile the unit you've created.
8. Go back to your main program and add the unit's name to the *uses* statement at the start of the program.

Ideally, you want your program organized so that when you are working on a particular aspect of it, you are modifying and recompiling a single module (unit or main program). This minimizes compile time; more importantly, it lets you work with smaller, more manageable chunks of code.
Initialization

Remember in all this that each unit can (optionally) have its own initialization code. This code is automatically executed when the program is first loaded. If your program uses several units, the initialization code for each unit is executed. The order of execution follows the order in which the units are listed in your program's uses statement; so if your program has the statement

`uses MyGlobals, MyUtils, EditLib, GraphLib;`

then the initialization section (if any) of MyGlobals will be called first, followed by that of MyUtils, then EditLib, then GraphLib.

To create an initialization section for a unit, put the keyword begin above the end that ends the implementation section. This defines the initialization section of your unit, much as the begin..end pair defines the main body of a program, a procedure, or a function. You can then put any Pascal code you want in here. It can reference everything declared in that unit, in both the public (interface) and private (implementation) sections; it can also reference anything from the interface portions of any units that this unit uses.

The Build and Make options

Turbo Pascal has an important feature to aid you in project management: a built-in Make utility. To understand its significance, let's look at the previous example again.

Suppose you have a program, MYAPP.PAS, which uses four units: MyGlobals, MyUtils, EditLib, and GraphLib. Those four units are contained in the text files MYGLOBAL.PAS, MYUTILS.PAS, EDITLIB.PAS, and GRAPHLIB.PAS, respectively. Furthermore, MyUtils uses MyGlobals, and EditLib and GraphLib use both MyGlobals and MyUtils.

When you compile MYAPP.PAS, it looks for the files MYGLOBAL.TPU, MYUTILS.TPU, EDITLIB.TPU, and GRAPHLIB.TPU, loads them into memory, links them with the code produced by compiling MYAPP.PAS, and writes everything out to MYAPP.EXE (if you're compiling to disk). So far, so good.
Suppose now you make modifications to EDITLIB.PAS. In order to recreate MYAPP.EXE, you need to recompile both EDITLIB.PAS and MYAPP.PAS. A little tedious, but no problem.

Now, suppose you modify the interface section of MYGLOBAL.PAS. To update MYAPP.EXE, you have to recompile all four units, as well as MYAPP.PAS. That means five separate compilations each time you make a change to MYGLOBAL.PAS—which could be enough to discourage you from using units at all. But wait...

The Make option

Turbo Pascal offers a solution. You can get the Make option (in the Compile menu) and Turbo Pascal to do all the work for you. The process is simple: After making any changes to any units or the main program, just Make the main program.

Turbo Pascal makes three kinds of checks.

1. **First, it checks and compares the date and time of the .TPU file for each unit used by the main program against the unit’s corresponding .PAS file.** If the .PAS file has been modified since the .TPU file was created, Turbo Pascal recompiles the .PAS file, creating an updated .TPU file. So, in the first example, if you modified EDITLIB.PAS and then recompiled MYAPP.PAS (using the Make option), Turbo Pascal would automatically recompile EDITLIB.PAS before compiling MYAPP.PAS.

2. **The second check is to see if you changed the interface portion of the modified unit.** If you did, then Turbo Pascal recompiles all other units using that unit.

As in the second example, if you modified the interface portion of MYGLOBAL.PAS and then recompiled MYAPP.PAS, Turbo Pascal would automatically recompile MYGLOBAL.PAS, MYUTILS.PAS, EDITLIB.PAS, and GRAPHLIB.PAS (in that order) before compiling MYAPP.PAS. However, if you only modified the implementation portion, then the other dependent units don’t need to be recompiled, since (as far as they’re concerned) you didn’t change that unit.

3. **The third check is to see if you changed any Include or .OBJ files (containing assembly language routines) used by any units.** If a given .TPU file is older than any of the Include or .OBJ files it links in, then that unit is recompiled. That way, if you modify and assemble some routines used by a unit, that unit is...
The Make option has no effect on units found in TURBO.TPL.

To use the Make option under the IDE, either select the Make command from the Compile menu, or press F9. To invoke it with the command-line compiler, use the option /M.

The Build option

The Build option (also in the Compile menu) is a special case of the Make option. When you compile a program using Build, it automatically recompiles all units used by that program (except, of course, those units in TURBO.TPL). This always brings everything up to date. You can invoke Build from the command line with the /B option.

The Stand-alone MAKE utility

Turbo Pascal places a great deal of power and flexibility at your fingertips. You can use it to manage large, complex programs that are built from numerous unit, source, and object files. And it can automatically perform a Build or a Make operation, recompiling units as needed. Understandably, though, Turbo Pascal has no mechanism for recreating .OBI files from assembly code routines (.ASM files) that have changed. To do that, you need to use a separate assembler. The question then becomes, how do you keep your .ASM and .OBI files updated?

The answer is simple: Use the MAKE utility that's included with Turbo Pascal. MAKE is an intelligent program manager that—given the proper instructions—does all the work necessary to keep your program up to date. In fact, MAKE can do far more than that. It can make backups, pull files out of different subdirectories, and even automatically run your programs should the data files that they use be modified. As you use MAKE more and more, you'll see new and different ways it can help you to manage your program development.

MAKE is a stand-alone utility; it is different from the Make and Build options that are part of both the IDE and the command-line compiler. Here's an example of how you might use it.

MAKE is documented in an online text file, UTILS.DOC.
A quick example

Suppose you’re writing some programs to help you display information about nearby star systems. You have one program—GETSTARS.PAS—that reads in a text file listing star systems, does some processing on it, then produces a binary data file with the resulting information in it.

GETSTARS.PAS uses three units: STARDEFS.TPU, which contains the global definitions; STARLIB.TPU, which has certain utility routines; and STARPROC.TPU, which does the bulk of the processing. The source code for these units is found in STARDEFS.PAS, STARLIB.PAS, and STARPROC.PAS, respectively.

The next issue is dependencies. STARDEFS.PAS doesn’t use any other units; STARLIB.PAS uses STARDEFS; STARPROC.PAS uses STARDEFS and STARLIB; and GETSTARS.PAS uses STARDEFS, STARLIB, and STARPROC.

Given that, to produce GETSTARS.EXE you would simply “make” GETSTARS.PAS. Turbo Pascal would recompile the units as needed.

Suppose now that you convert a number of the routines in STARLIB.PAS into assembly language, creating the files SLIB1.ASM and SLIB2.ASM, then use Turbo Assembler to create SLIB1.OBJ and SLIB2.OBJ. Each time STARLIB.PAS is compiled, it links in those .OBJ files. And, in fact, Turbo Pascal is smart enough to recompile STARLIB.PAS if STARLIB.TPU is older than either of those .OBJ files.

However, what if either .OBJ file is older than the .ASM file upon which it depends? That means that the particular .ASM file needs to be re-assembled. Turbo Pascal can’t assemble those files for you, so what do you do?

You create a make file and let MAKE do the work for you. A make file consists of dependencies and commands. The dependencies tell MAKE which files a given file depends upon; the commands tell MAKE how to create that given file from the other ones.
Creating a makefile

Your makefile for this project might look like this:

```
getstars.exe: getstars.pas stardefs.pas starlib.pas slib1.asm \
    slib2.asm slib1.obj slib2.obj

tpc getstars /m
```

`slib1.obj: slib1.asm
   TASM slib1.asm slib1.obj`

`slib2.obj: slib2.asm
   TASM slib2.asm slib2.obj`

Okay, so this looks a bit cryptic. Here's an explanation:

- The first two lines tell MAKE that GETSTARS.EXE depends on three Pascal, two assembly language, and two .OBJ files (the backslash at the end of line 1 tells MAKE to ignore the line break and continue the dependency definition on the next line).

- The third line tells MAKE how to build a new GETSTARS.EXE. Notice that it simply invokes the command-line compiler on GETSTARS.PAS and uses the built-in Turbo Pascal Make facility (/M option).

- The next two lines (ignoring the blank line) tell MAKE that SLIB1.OBJ depends on SLIB1.ASM and show MAKE how to build a new SLIB1.OBJ.

- Similarly, the last two lines define the dependencies (only one file, actually) and MAKE procedures for the file SLIB2.OBJ.

Using MAKE

Let's suppose you've created this Make file using the editor in the Turbo Pascal IDE (or any other ASCII editor) and saved it as the file STARS.MAK. You would then use it by issuing the command

```
make -fstars.mak
```

where `-f` is an option telling MAKE which file to use. First, it checks to see if SLIB2.OBJ is older than SLIB2.ASM. If it is, then MAKE issues the command

```
TASM SLIB2.asm SLIB2.obj
```

which assembles SLIB2.ASM, creating a new version of SLIB2.OBJ. It then makes the same check on SLIB1.ASM and issues the same command if needed. Finally, it checks all of the dependencies for GETSTARS.EXE and, if necessary, issues the command.
tpc getstars /m

The /M option tells Turbo Pascal to use its own internal MAKE routines, which will then resolve all unit dependencies, including recompiling STARLIB.PAS if either SLIB1.OBJ or SLIB2.OBJ is newer than STARLIB.TPU.

Conditional compilation

To make your job easier, Turbo Pascal 6.0 offers conditional compilation. This means that you can now decide what portions of your program to compile based on options or defined symbols. For a complete reference to conditional directives, refer to Chapter 21, "Compiler directives," in the *Programmer's Guide.*

The conditional directives are similar in format to the compiler directives you're accustomed to; in other words, they take the format

```
{$directive arg}
```

where *directive* is the directive (such as DEFINE, IFDEF, and so on), and *arg* is the argument, if any. Note that there must be a separator (blank, tab) between *directive* and *arg*. Table 6.1 lists all the conditional directives, with their meanings.

<table>
<thead>
<tr>
<th>Directive</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>{$DEFINE symbol}</td>
<td>Defines symbol for other directives</td>
</tr>
<tr>
<td>{$UNDEF symbol}</td>
<td>Removes definition of symbol</td>
</tr>
<tr>
<td>{$IFDEF symbol}</td>
<td>Compiles following code if symbol is defined</td>
</tr>
<tr>
<td>{$IFNDEF symbol}</td>
<td>Compiles following code if symbol is not defined</td>

</tr>
<tr>

<td>Compiles following code if previous IFxxx is not True</td>
</tr>
<tr>
<td>{$ENDIF}</td>
<td>Marks end of IFxxx or ELSE section</td>
</tr>
</tbody>
</table>

The DEFINE and UNDEF directives

The IFDEF and IFNDEF directives test to see if a given symbol is defined. These symbols are defined using the DEFINE directive and undefined UNDEF directives. (You can also define symbols on the command line and in the IDE.)

To define a symbol, insert the directive

```
{$DEFINE symbol}
```
into your program. symbol follows the usual rules for identifiers as far as length, characters allowed, and other specifications. For example, you might write

\{\$DEFINE debug\}

This defines the symbol debug for the remainder of module being compiled, or until the statement

\{\$UNDEF debug\}

is encountered. As you might guess, UNDEF "undefines" a symbol. If the symbol isn't defined, UNDEF has no effect.

Defining at the command line

If you're using the command-line version of Turbo Pascal (TPC.EXE), you can define conditional symbols on the command line itself. TPC accepts a /D option, followed by a list of symbols separated by semicolons:

```
  tpc myprog /Ddebug;test;dump
```

This would define the symbols debug, test, and dump for the program MYPROG.PAS. Note that the /D option is cumulative, so that the following command line is equivalent to the previous one:

```
  tpc myprog /Ddebug /Dtest /Ddump
```

Defining in the IDE

Conditional symbols can be defined in the Conditional Defines input box (Options | Compiler). Multiple symbols can be defined by entering them in the input box, separated by semicolons. The syntax is the same as that of the command-line version.

Predefined symbols

In addition to any symbols you define, you also can test certain symbols that Turbo Pascal has defined. Table 6.2 lists these symbols; let's look at each in a little more detail.

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>VER60</td>
<td>Always defined (TP 4.0 has VER40 defined, etc.)</td>
</tr>
<tr>
<td>MSDOS</td>
<td>Always defined</td>
</tr>
<tr>
<td>CPU86</td>
<td>Always defined</td>
</tr>
<tr>
<td>CPU87</td>
<td>Defined if an 8087 is present at compile time</td>
</tr>
</tbody>
</table>
The VER60 symbol

The symbol VER60 is always defined for Turbo Pascal 6.0. In a similar fashion, VER40 is defined for version 4.0 of Turbo Pascal, VER50 for version 5.0 and so on. Future versions will have corresponding predefined symbols; for example, version 6.5 would have VER65 defined, version 7.0 would have VER70 defined, and so on. This allows you to create source code files that can use future enhancements while maintaining compatibility with older versions.

The MSDOS and CPU86 symbols

These symbols are always defined (at least for Turbo Pascal 6.0 running under DOS). The MSDOS symbol indicates you are compiling under the DOS operating system. The CPU86 symbol means you are compiling on a computer using an Intel iAPx86 (8088, 8086, 80186, 80286, 80386, 80486) processor. As future versions of Turbo Pascal for other operating systems and processors become available, they will have similar symbols indicating which operating system and/or processor is being used. Using these symbols, you can create a single source code file for more than one operating system or hardware configuration.

The CPU87 symbol

Turbo Pascal 6.0 supports floating-point operations in two ways: hardware and software. If you have an 80x87 math coprocessor installed in your computer system, you can use the IEEE floating-point types (Single, Double, Extended, comp), and Turbo Pascal will produce direct calls to the math chip. If you don’t have an 8087, you can still use the IEEE types by instructing Turbo Pascal to emulate the 8087 in software. Otherwise, you can just use the standard floating-point type real (6 bytes in size), and Turbo Pascal will support all your operations with software routines. Use the $N and $E directives to indicate which you wish to use.

When you load the Turbo Pascal compiler, it checks to see if an 80x87 chip is installed. If it is, then the CPU87 symbol is defined; otherwise, it’s undefined. You might then have the following code at the start of your program:

```pascal
{$N+}
{$IFDEF CPU87}
{$E+}
{$ENDIF}
```

{ Always use IEEE floating point }
{ If there’s no 80x87 present }
{ No hardware: Use emulation library }
The IFxxx, ELSE, and EndIF symbols

The idea behind conditional directives is that you want to select some amount of source code to be compiled if a particular symbol is (or is not) defined or if a particular option is (or is not) enabled. The general format follows:

```
{$IFxxx}
  source code
{$ENDIF}
```

where IFxxx is IFDEF, IFNDEF, or IFOPT, followed by the appropriate argument, and source code is any amount of Turbo Pascal source code. If the expression in the IFxxx directive is True, then source code is compiled; otherwise, it is ignored as if it had been commented out of your program.

Often you have alternate chunks of source code. If the expression is True, you want one chunk compiled, and if it's False, you want the other one compiled. Turbo Pascal lets you do this with the $ELSE directive:

```
{$IFxxx}
  source code A
{$ELSE}
  source code B
{$ENDIF}
```

If the expression in IFxxx is True, source code A is compiled; otherwise source code B is compiled.

Note that all IFxxx directives must be completed within the same source file, which means they cannot start in one source file and end in another. However, an IFxxx directive can encompass an Include file:

```
{$IFxxx}
{$I file1.pas}
{$ELSE}
{$I file2.pas}
{$ENDIF}
```

That way, you can select alternate Include files based on some condition.

You can nest IFxxx..ENDIF constructs so that you can have something like this:
The IFDEF and IFNDEF directives

You've learned how to define a symbol, and also that there are some predefined symbols. The **IFDEF** and **IFNDEF** directives let you conditionally compile code based on whether those symbols are defined or undefined. You saw this example earlier:

```pascal
{$IFDEF CPU87} { If there's an 80x87 present }
{$N+,E-} { Then use the inline 8087 code }
{$ELSE} { Else use the emulation library }
{$N+,E+} { If an 8087 math coprocessor is present when your program is compiled. Then select direct calls to the 8087. Otherwise, use the software 8087 emulation. }
{$ENDIF}
```

By putting this in your program, you can automatically select the **$N** option if an 8087 math coprocessor is present when your program is compiled. That's an important point: This is a compile-time option. If there is an 8087 coprocessor in your machine when you compile, then your program will be compiled with the **$N+** and **E-** compiler directives, selecting direct calls to the 8087. Otherwise, it will be compiled with the **$N+** and **$E+** directives, using the software 8087 emulation. If you compile this program on a machine with an 8087, you can't run the resulting .EXE file on a machine without an 8087. (Of course, a program compiled using **$N+,E+** will run on any system and use emulation only if no 8087 hardware is detected.)

It is also common to use the **IFDEF** and **IFNDEF** directives to insert debugging information into your compiled code. For example, if you put the following code at the start of each unit:

```pascal
{$IFDEF debug} { First IF directive }
... { Second IF directive }
... { Terminates second IF directive }
... { Terminates first IF directive }
```

and the following directive at the start of your program:

```pascal
{$DEFINE debug} { Define symbol }
```
and compile your program, then complete debugging information will be generated by the compiler for use with the integrated debugger or the standalone Turbo Debugger. In a similar fashion, you can have sections of code that you want compiled only if you are debugging; in that case, you would write

\[
\begin{align*}
\{ & \text{IFDEF } debug \\
 & \text{source code} \\
\{ & \text{ENDIF}
\end{align*}
\]

where \textit{source code} will be compiled only if \textit{debug} is defined at that point.

---

**The IFOPT directive**

You may want to include or exclude code, depending upon which compiler options (range-checking, I/O-checking, numeric-processing, and so on) have been selected. Turbo Pascal lets you do that with the \textbf{IFOPT} directive, which takes two forms:

\[
\begin{align*}
\{ & \text{IFOPT } x+ \\
\{ & \text{IFOPT } x- \\
\end{align*}
\]

where \textit{x} is one of the compiler options: \textit{SA, SB, SD, SE, SF, SG, SI, SL, SN, SO, SR, SS, SV, SX} (see Chapter 21 in the \textit{Programmer's Guide}, “Compiler directives,” for a complete description). With the first form, the following code is compiled if the compiler option is currently enabled; with the second, the code is compiled if the option is currently disabled. So, as an example, you could have the following:

\[
\begin{align*}
\text{var} \\
\{ & \text{IFOPT N+} \\
 & \text{Radius,Circ,Area: Double;} \\
\{ & \text{ELSE} \\
 & \text{Radius,Circ,Area: Real;} \\
\{ & \text{ENDIF}
\end{align*}
\]

This selects the data type for the listed variables based on whether or not 8087 support is enabled.

An alternate example might be
Assign(F,Filename);
Reset(F);
{$IFOPT I-}
IOCheck;
{$ENDIF}

where IOCheck is a user-written procedure that gets the value of IOResult, and prints out an error message as needed. There's no sense calling IOCheck if you've selected the {$I+} option since, if there's an error, your program will halt before it ever calls IOCheck.

Optimizing code

A number of compiler options influence both the size and the speed of the code. This is because they insert error-checking and error-handling code into your program. It's best to enable them while you are developing your program, but you may want to disable them for your final version. Here are those options, with their settings for code optimization (the default settings are stated last):

- {$A+} enables word alignment of variables and type constants; this results in faster memory access on 80x86 systems. The default is {$A+}.
- {$B-} uses short-circuit Boolean evaluation. This produces code that can run faster, depending upon how you set up your Boolean expressions. The default is {$B-}.
- {$E-} disables linking with a run-time library that emulates an 8087 numeric coprocessor if one isn't present. This forces Turbo Pascal to use either 8087 hardware or the standard 6-byte type real, depending on the state of the $N numeric processing switch. The default is {$E-}.
- {$G+} uses additional instructions of the 80286 to improve code generation; programs compiled this way cannot run on 8088 and 8086 processors.
- {$I-} turns off I/O error-checking. By calling the predefined function IOResult, you can handle I/O errors yourself. The default is {$I+}.
- {$N-} generates code capable of performing all floating-point operations using the built-in 6-byte type real. When the $N switch is on, Turbo Pascal will use 8087 hardware or emulation
in software instead. If you compile a program and all the units it uses with \texttt{\$N-}, an 8087 run-time library is not required and Turbo Pascal ignores the emulation switch directive \texttt{\$E}. The default is \texttt{\$N-}.

- \texttt{\$R-} turns off range checking. This prevents code generation to check for array subscripting errors and assignment of out-of-range values. The default is \texttt{\$R-}.

- \texttt{\$S-} turns off stack-checking. This prevents code generation to ensure that there is enough space on the stack for each procedure or function call. The default is \texttt{\$S+}.

- \texttt{\$V-} turns off checking of \texttt{var} parameters that are strings. This lets you pass actual parameter strings that are of a different length than the type defined for the formal \texttt{var} parameter. The default is \texttt{\$V+}.

- \texttt{\$X+} enables functions calls to be used as statements; the result of a function call can be discarded.

See Chapter 21 of the \textit{Programmer's Guide} for more information on compiler directives.

Optimizing your code using these options has two advantages. First, it usually makes your code smaller and faster. Second, it allows you to get away with something that you couldn't normally. However, they all have corresponding risks as well, so use them carefully, and reenable them if your program starts behaving strangely.

Note that besides embedding the compiler options in your source code directly, you can also set them using the \textit{Options | Compiler} menu in the IDE or the \texttt{/SX} option in the command-line compiler (where \texttt{X} represents a letter for a compiler directive).
Chapter 7, The IDE reference

Turbo Pascal makes it easy and efficient for you to write, edit, compile, link, and debug your programs. That's what Borland's programmer's platform (also known as the integrated environment, or IDE for short) is all about.

The Turbo Pascal IDE furnishes these extras to make program writing even smoother:

- multiple, movable, resizable windows
- mouse support
- multi-file editing of files up to 1 Mb in size
- dialog boxes
- cut-and-paste commands (with copying allowed from the Help window and between Edit windows)
- search-and-replace capabilities
- print capabilities
- editor macro language

This chapter tells you briefly how to start and exit Turbo Pascal and then launches into detail about the individual menu items, dialog boxes, buttons, and so on. For an introduction to the basic components of the IDE, you can

- Go to Chapter 1. This chapter provides you with some general information about the IDE and then gets you started programming in the environment.
Run TPTOUR. This interactive tutorial emulates the Turbo Pascal IDE to show you how to open files, edit them, and compile, run and debug programs, plus learn general window-management skills.

Take advantage of Turbo Pascal's extensive online help system. You can get information about any aspect of the IDE in a keystroke (F1); specific language help is at your fingertips too (press Ctrl-F1 while you're in the Edit window).

Starting and exiting

Starting Turbo Pascal is simple. You just move to your Turbo Pascal directory and type TURBO at the DOS command line. If you like, you can use one or more options (and file names) along with the TURBO command. These options make use of dual monitors, expanded memory, RAM disks, LCD screens, the EGA palette, and more.

Command-line options

The command-line options for Turbo Pascal's IDE are /C, /D, /E, /G, /L, /N, /P, /SX, /T, /X. These options use this syntax:

turbo [options] files

Placing a + (or a space) after the directive turns it on; placing a - after it turns it off. For example,

turbo -g -p- myfile

enables graphics memory save and disables palette swapping.

The /C option

If you use the /C option followed by a configuration file name, Turbo Pascal will load in that configuration file when it starts up.

The /D option

The /D option causes Turbo Pascal to work in dual monitor mode if it detects appropriate hardware (for example, a monochrome card and a color card); otherwise, the /D option is ignored. Use dual monitor mode when you run or debug a program, or shell to DOS (File | DOS Shell).

If your system has two monitors, DOS treats one monitor as the active monitor. Use the DOS MODE command to switch between...
the two monitors (*MODE CO80*, for example, or *MODE MONO*). In dual
monitor mode, the normal Turbo Pascal screen will appear on the
inactive monitor, and program output will go to the active
monitor. So when you type *TURBO /D* at the DOS prompt on one
monitor, Turbo Pascal will come up on the other monitor. When
you want to test your program on a particular monitor, exit Turbo
Pascal, switch the active monitor to the one you want to test with,
and then issue the *TURBO /D* command again. Program output will
then go to the monitor where you typed the *TURBO* command.

Keep the following in mind when using the */D* option:

- Don't change the active monitor (by using the DOS *MODE*
  command, for example) while you are in a DOS shell (File | DOS
  Shell).
- User programs that directly access ports on the inactive
  monitor's video card are not supported, and can cause
  unpredictable results.
- When you run or debug programs that explicitly make use of
dual monitors, do not use the Turbo Pascal dual monitor option
(*/D*).

The */E* option

Use the */E* option to change the size of the editor heap. The
default size is 28K, which is the minimum setting; the maximum
is 128K. Making the editor heap larger than 28K will only
improve IDE performance if you're using a slow disk as a swap
device. If you have EMS or have placed your swap file on a RAM
disk (see */S* option), then don't change the default setting.

The */G* option

Use the */G* option to enable a full graphics memory save while
you're debugging graphics programs on EGA, VGA, and MCGA
systems. With Graphics Screen Save on, the IDE will reserve
another 8K for the buffer (which will be placed in EMS if
available).

The */L* option

Use the */L* option if you're running Turbo Pascal on an LCD
screen.

The */N* option

Use the */N* option to enable or disable CGA snow checking; the
default setting is on. Disable this option if you're using a CGA
that doesn't experience snow during screen updates. This option
has no effect unless you're using a CGA.

Chapter 7, The IDE reference 175
The /O option  Use the /O option to change the IDE's overlay heap size. The default is 112K. The minimum size you can adjust this to is 64K; the maximum is 256K. If you have EMS, you can decrease the size of the overlay heap without degrading IDE performance and therefore free more memory for compiling and debugging your programs.

The /P option  Use the /P option, which controls palette swapping on EGA video adapters, when your program modifies the EGA palette registers. The EGA palette will be restored each time the screen is swapped. In general, you don't need to use this option unless your program modifies the EGA palette registers or unless your program uses BGI to change the palette.

The /S option  If your system has no EMS available, use the /S option to specify the drive and path of a "fast" swap area, such as a RAM disk (for example, /Sd: \, where d is the drive). If no swap directory is specified, a swap file is created in the current directory.

The /T option  Disable the /T option if you don't want the IDE to load TURBO.TPL at startup. If TURBO.TPL is not loaded, you'll need the System unit (SYSTEM.TPU) available in order to compile or debug programs. You can increase the IDE's capacity by disabling the /T option and extracting SYSTEM.TPU from TURBO.TPL (using the TPUMOVER, see UTILS.DOC on your distribution disks for details).

The /W option  Use the /W option if you want to change the window heap size. The default setting is 32K. The minimum setting is 24K; the maximum is 64K. Reduce the window heap size to make more memory available for your programs if you don't need a lot of windows open on your desktop. The default provides for good capacity and ample window space.

The /X option  Disable the /X option if you don't want the IDE to use EMS. The default setting is on. When this option is enabled, the IDE improves performance by placing overlaid code, editor data, and other system resources in EMS.
Exiting Turbo Pascal

There are two ways to leave Turbo Pascal:

- To exit Turbo Pascal "permanently," choose File | Exit (or press Alt-X). If you've made changes that you haven't saved, Turbo Pascal prompts you whether you want to save your programs before exiting.

- To leave Turbo Pascal to enter commands at the DOS command line, choose File | DOS Shell. Turbo Pascal stays in memory but transfers you to DOS. You can enter any normal DOS commands, and even run other programs. When you're ready to return to Turbo Pascal, type EXIT at the command line and press Enter. Turbo Pascal reappears just as you left it.

≡ (System) menu

Alt Space

The ≡ menu provides three general system-wide commands (About, Refresh Display, and Clear Desktop).

About displays a dialog box with copyright and version information for Turbo Pascal. Press Esc or Spacebar or click OK (or press Enter) to close the box.

You can use this option to restore the IDE screen. This is handy if your program has accidentally overwritten the IDE's screen and you need to restore it.

Choose ≡ | Clear Desktop to close all windows and clear all history lists.
File menu

The File menu lets you open and create program files in Edit windows. The menu also lets you save your changes, perform other file functions, shell to DOS, and quit.

Open

The File | Open command displays a file-selection dialog box for you to select a program file to open in an Edit window:

The dialog box contains an input box, a file list, buttons labeled Open, Replace, Cancel, and Help, and an information panel that describes the selected file. Now you can do any of these actions:

- Type in a full file name and choose Replace or Open. Open loads the file into a new Edit window. Replace replaces the contents of the window with the selected file; an Edit window must be active if you do this.
- Type in a file name with wildcards, which filters the file list to match your specifications.
- Press ↓ to choose a file specification from a history list of file specifications you've entered earlier.
- View the contents of different directories by selecting a directory name in the file list.

The input box lets you enter a file name explicitly or lets you enter a file name with standard DOS wildcards (* and ?) to filter the names appearing in the history list box. If you enter the entire name and press Enter, Turbo Pascal opens it. (If you enter a file name that Turbo Pascal can't find, it automatically creates and opens a new file with that name.)
If you choose Replace instead of Open, the selected file replaces the file in the active Edit window instead of opening up a new window.

Using the File list box

You can also type a lowercase letter to search for a file name and an uppercase letter to search for a directory name.

If you press ↓ when the cursor is blinking in the input box, a scrollable history list drops down below the box. Choose a name from the list by double-clicking it or selecting it with the arrow keys and pressing Enter.

Once you've typed in or selected the file you want, choose the Open button (choose Cancel if you change your mind). You can also just press Enter once the file is selected, or you can double-click the file name.

The File list box displays all file names in the current directory that match the specifications in the input box, displays the parent directory, and displays all subdirectories. Click the list box or press Tab until the list box name is highlighted. You can now press ↓ or ↑ to select a file name, and then press Enter to open it. You can also double-click any file name in the box to open it. You might have to scroll the box to see all the names. If you have more than one pane of names, you can also use → and ←.

The file information panel at the bottom of the Open a File dialog box displays path name, file name, date, time, and size of the file you've selected in the list box. (None of the items on this panel are selectable.) As you scroll through the list box, the panel is updated for each file.

New

The File | New command lets you open a new Edit window with the default name NONAME.xx.PAS (the xx stands for a number from 00 to 99). These NONAME files are used as a temporary edit buffer; Turbo Pascal prompts you to name a NONAME file when you save it.

Save

The File | Save command saves the file in the active Edit window to disk. (This menu item is disabled if there's no active Edit window.) If the file has a default name (NONAME00.PAS, or the like), Turbo Pascal opens the Save File As dialog box to let you rename and save it in a different directory or on a different drive. This dialog box is identical to the one opened for the Save As command, described next.
Save As

The File | Save As command lets you save the file in the active Edit window under a different name, in a different directory, or on a different drive. When you choose this command, you see the Save File As dialog box:

![Save File As dialog box](image)

Enter the new name, optionally with drive and directory, and click or choose OK. All windows containing this file are updated with the new name. If you pick an existing file name, that file will be overwritten.

Save All

The File | Save All command works just like the Save command except that it saves the contents of all modified files, not just the file in the active Edit window. This command is disabled if no Edit windows are open.

Change Dir

The File | Change Dir command lets you specify a drive and a directory to make current. The current directory is the one Turbo Pascal uses to save files and to look for files. (When using relative paths in Options | Directories, they are relative to this current directory only.)

Here is what the Change Directory dialog box looks like:
There are two ways to change directories:

- Type in the path of the new directory in the input box and press Enter, or
- Choose the directory you want in the Directory tree (if you’re using the keyboard, press Enter to make it the current directory), then choose OK or press Esc to exit the dialog box.

If you choose the OK button, your changes will be made and the dialog box put away. If you choose the Chdir button, the Directory Tree list box changes to the selected directory and displays the subdirectories of the currently highlighted directory (pressing Enter or double-clicking on that entry gives you the same result). If you change your mind about the directory you’ve picked and you want to go back to the previous one (and you’ve yet to exit the dialog box), choose the Revert button.

---

Print

The File | Print command lets you print the contents of the active Edit window. Turbo Pascal expands tabs (replaces tab characters with the appropriate number of spaces) and then sends it to the DOS print handler. This command is disabled if the active window cannot be printed. Use Ctrl-K P to print selected text only.

---

Get Info

The File | Get Info command displays a box with information on the current file.
The information here is for display only; you can't change any of the settings in this box. After reviewing the information in this box, press Enter to put the box away.

**DOS Shell**

The File | DOS Shell command lets you temporarily exit Turbo Pascal to enter a DOS command or program. To return to Turbo Pascal, type EXIT and press Enter.

You may find that when you're debugging, there's not enough memory to execute this command. If that's the case, terminate the debug session by choosing Run | Program Reset (Ctrl-F2).

**Note:** In dual monitor mode, the DOS command line appears on the Turbo Pascal screen rather than the User Screen. This allows you to switch to DOS without disturbing the output of your program. Since your program output is available on one monitor in the system, Window | User Screen and Alt-F5 are disabled.

**Exit**

The File | Exit command exits Turbo Pascal, removes it from memory, and returns you to the DOS command line. If you have made any changes that you haven't saved, Turbo Pascal asks you if you want to save them before exiting.

**Edit menu**

The Edit menu lets you cut, copy, and paste text in Edit windows. You can also open a Clipboard window to view or edit its contents.
Before you can use most of the commands on this menu, you need to know about selecting text (because most editor actions apply to selected text). Selecting text means highlighting it. You can select text either with keyboard commands or with a mouse; the principle is the same even though the actions are different.

**From the keyboard you can use any of these methods:**

- Press `Shift` while pressing any arrow key.
- To select text from the keyboard, press `Ctrl-K B` to mark the start of the block. Then move the cursor to the end of the text and press `Ctrl-K K`.
- To select a single word, move the cursor to the word and press `Ctrl-K T`.
- To select an entire line, press `Ctrl-K L`.

**With a mouse:**

- To select text with a mouse, drag the mouse pointer over the desired text. If you need to continue the selection past a window’s edge, just drag off the side and the window will automatically scroll.
- To select a single line, double-click anywhere in the line.
- To select text line-by-line, click-drag over the text (that is, click once and then quickly press the mouse button again and begin to drag).
- To extend or reduce the selection, Shift-click anywhere in the document (that is, hold `Shift` and click).

Once you have selected text, the commands in the **Edit** menu become available, and the Clipboard becomes usable.

The Clip**board is the magic behind cutting and pasting. It’s a special window in Turbo Pascal that holds text that you have cut or copied, so you can paste it elsewhere. The Clipboard works in close concert with the commands in the **Edit** menu.

Here’s an explanation of each command in the **Edit** menu.

---

**Restore Line**

The **Edit | Restore Line** command takes back the last editing command you performed on a line (including typing text on a blank line or `Ctrl-Y`). **Restore Line** works only on the last modified or deleted line.
Cut

The Edit | Cut command removes the selected text from your document and places the text in the Clipboard. You can then paste that text into any other document (or somewhere else in the same document) by choosing Paste. The text remains selected in the Clipboard so that you can paste the same text many times.

Copy

The Edit | Copy command leaves the selected text intact but places an exact copy of it in the Clipboard. You can then paste that text into any other document by choosing Paste. You can also copy text from a Help window: With the keyboard, use Shift and the arrow keys; with the mouse, click and drag the text you want to copy.

Paste

The Edit | Paste command inserts text from the Clipboard into the current window at the cursor position. The text that is actually pasted is the currently marked block in the Clipboard window.

Copy Example

The Edit | Copy Example command copies the preselected example text in the current Help window to the Clipboard. The examples are already predefined as pastable blocks, so you don’t need to bother with marking the example you want.

Show Clipboard

The Edit | Show Clipboard command opens the Clipboard window, which stores the text you cut and copy from other windows. The text that’s currently selected (highlighted) is the text that gets pasted. And you can edit the Clipboard so that the text you paste is precisely the text you want.

The Clipboard window is just like other Edit windows except when you cut or copy text. When you select text in the Clipboard window and choose Cut or Copy, the selected text immediately appears at the bottom of the window. (Remember, any text that
you cut or copy is appended to the end of the Clipboard—so you can paste it later.)

Clear

The Edit | Clear command removes the selected text but does not put it into the Clipboard. This means you cannot paste the text as you could if you had chosen Cut or Copy. The cleared text is not retrievable. You can clear the Clipboard itself by selecting all the text in the Clipboard, then selecting Edit | Clear.

Search menu

The Search menu lets you search for text, procedure declarations, and error locations in your files.

Find

The Search | Find command displays the Find dialog box, which lets you type in the text you want to search for and set options that affect the search. (Ctrl-Q F is another shortcut for this command.)

Figure 7.5
The Find dialog box

The Find dialog box contains several buttons and check boxes.

Options

You can choose from three items in the Options check boxes:

- [ ] Case sensitive
  Check the Case Sensitive box if you do want Turbo Pascal to differentiate uppercase from lowercase.

- [ ] Whole words only
  Check the Whole Words Only box if you want Turbo Pascal to search for words only (that is, a string with punctuation or space characters on both sides).
Check the Regular Expression box if you want Turbo Pascal to recognize GREP-like wildcards in the search string. The wildcards are ^, $, ., *, +, [ ], and \. Here's what they mean:

- ^: A circumflex at the start of the string matches the start of a line.
- $: A dollar sign at the end of the expression matches the end of a line.
- .: A period matches any character.
- *: A character followed by an asterisk matches any number of occurrences (including zero) of that character. For example, bo* matches bot, b, boo, and also be.
- +: A character followed by a plus sign matches any number of occurrences (but not zero) of that character. For example, bo+ matches bot and boo, but not be or b.
- [:]: Characters in brackets match any one character that appears in the brackets but no others. For example [bot] matches b, o, or t.
- [^]: A circumflex at the start of the string in brackets means not. Hence, [^bot] matches any characters except b, o, or t.
- [-]: A hyphen within the brackets signifies a range of characters. For example, [b-o] matches any character from b through o.
- \: A backslash before a wildcard character tells Turbo Pascal to treat that character literally, not as a wildcard. For example, \^ matches ^ and does not look for the start of a line.

Enter the string in the input box and choose OK to begin the search, or choose Cancel to forget it. If you want to enter a string that you searched for previously, press ↓ to choose from the history list.

You can also pick up the word that your cursor is currently on in the Edit window and use it in the Find box by simply invoking Find from the Search menu. You can take additional characters from the text by pressing →.

Choose from the Direction radio buttons to decide which direction you want Turbo Pascal to search—starting from the origin (settable with the Origin radio buttons).

Choose from the Scope radio buttons to determine how much of the file to search in. You can search the entire file (Global) or only the selected text.
Origin

Choose from the Origin radio buttons to determine where the search begins. When Entire Scope is chosen, the Direction radio buttons determine whether the search starts at the beginning or the end of the chosen scope. You choose the range of scope you want with the Scope radio buttons.

Replace

Figure 7.6

The Replace dialog box contains several radio buttons and check boxes—many of which are identical to the Find dialog box, discussed previously. An additional checkbox, Prompt on Replace, controls whether you're prompted for each change.

After you've entered the search string and the replacement string in the input boxes, choose OK or Change All to begin the search, or choose Cancel to forget it. If you want to enter a string you used previously, press ↓ to choose from the history list.

If Turbo Pascal finds the specified text, it asks you if you want to make the replacement. If you choose OK, it will find and replace only the first instance of the search item. If you choose Change All, it replaces all occurrences found, as defined by Direction, Scope, and Origin.

Like in the Find dialog box, you can pick up the word your cursor is currently on in the Edit window and use it in the Text to Find input box by simply invoking Find or Replace from the Search menu. And you can add more text from the Edit window by pressing →.
Search | Search Again

Search Again

The **Search | Search Again** command repeats the last **Find** or **Replace** command. All settings you made in the last dialog box used (Find or Replace) remain in effect when you choose **Search Again**.

Go to Line Number

The **Search | Go to Line Number** command prompts you for the line number you want to find:

![Go to Line Number dialog box](image)

Turbo Pascal displays the current line number and column number in the lower left corner of every Edit window.

Find Procedure

The **Search | Find Procedure** command displays a dialog box for you to enter the name of a procedure or function to search for. This command is available only during a debugging session.

![Find Procedure dialog box](image)

Enter the name of a procedure or press ↓ to choose a name from the history list. As opposed to the **Search | Find** command, this command finds the declaration of the procedure, not instances of its use.

Find Error

The **Search | Find Error** command finds the location of a run-time error. When a run-time error occurs, the address in memory of where it occurred is given in the format `seg:ofs`. When you return to the IDE, Turbo Pascal automatically locates the error for you. This command allows you to find the error again, given the `seg` and `ofs` values.
For Find Error to work, you must set the Debugging check box to Integrated (in the Options | Debugger dialog box).

If run-time errors occur in a program running within the IDE, the default values for the error address are set automatically. This allows you to relocate the error after changing files. (Note that if you just move around in the same file, you can get back to the error location with the Ctrl-Q W command.)

When run-time errors occur under DOS, record the segment and offset displayed onscreen. Then load the main program into the editor or specify it as the Main File. Be sure to set the Destination to Disk, then type in the segment offset value.

When you enter the error address, you must give it in hexadecimal segment and offset notation. The format is "xxxx:yyyy"; for example, "2BE0:FFD4."

Run menu

The Run menu's commands run your program, and also start and end debugging sessions.

Run

The Run | Run command runs your program, using any parameters you pass to it with the Run | Parameters command. If the source code has been modified since the last compilation, the compiler's built-in project manager will automatically do a make and link your program.

If you don’t want to debug your program, you can compile and link it with both the Debugging check boxes unchecked (which gives the program more room to run) in the Options | Debugger dialog box. If you compile your program with this check box set to Integrated, the resulting executable code will contain debugging information that will affect the behavior of the Run | Run command in the following ways:

If you have not modified your source code since the last compilation,

• the Run | Run command causes your program to run to the next breakpoint, or to the end if no breakpoints have been set.
If you have modified your source code since the last compilation,

• and if you’re already stepping through your program using the Run I Step Over or Run I Trace Into commands, Run I Run prompts you whether you want to rebuild your program:
  • If you answer yes, the built-in project manager will make and link your program, and set it to run from the beginning.
  • If you answer no, your program runs to the next breakpoint or to the end if no breakpoints are set.

• and if you are not in an active debugging session, the built-in project manager makes your program and sets it to run from the beginning.

Pressing Ctrl-Break causes Turbo Pascal to stop execution on the next source line in your program. If Turbo Pascal is unable to find a source line, a second Ctrl-Break will terminate the program and return you to the IDE.

---

**Program Reset**

Run I Program Reset command stops the current debugging session, releases memory your program has allocated, and closes any open files that your program was using.

---

**Go to Cursor**

The Run I Go to Cursor command runs your program from the run bar (the highlighted bar in your code) to the line the cursor is on in the current Edit window. If the cursor is at a line that does not contain an executable statement, the command displays a warning. Run I Go to Cursor can also initiate a debug session.

Go to Cursor does not set a permanent breakpoint, but it does allow the program to stop at a permanent breakpoint if it encounters one before the line the cursor is on. If this occurs, you must choose the Go to Cursor command again.

Use Go to Cursor to advance the run bar to the part of your program you want to debug. If you want your program to stop at a certain statement every time it reaches that point, set a breakpoint on that line.

Note that if you position the cursor on a line of code that is not executed, your program will run to the next breakpoint or the end
if no breakpoints are encountered. You can always use Ctrl-Break to stop a running program.

**Trace Into**

The Run | Trace Into command runs your program statement by statement. When it reaches a procedure call, it executes each statement within the procedure, instead of executing the procedure as a single step (see Run | Step Over). If a statement contains no calls to procedures accessible to the debugger, Trace Into stops at the next executable statement.

Use the Trace Into command to move the run bar into a procedure called by the procedure you are now debugging. If the statement contains a call to a procedure accessible to the debugger, Trace Into halts at the beginning of the procedure's definition. Subsequent Trace Into or Step Over commands run the statements in the procedure's definition. When the debugger leaves the procedure, it resumes evaluating the statement that contains the call:

```plaintext
if Min <= Max then
  DoSomething;
```

The Trace Into command recognizes only procedures defined in a source file compiled with two options set on:

- In the Compiler Options dialog box (Options | Compiler), check Debug Information.
- In the Debugger dialog box (Options | Debugger), check Integrated.

**Step Over**

The Run | Step Over command executes the next statement in the current procedure. It does not trace into calls to lower-level procedures, even if they are accessible to the debugger.

Use Step Over to run the procedure you are now debugging, one statement at a time without branching off into other procedures.

**Parameters**

The Run | Parameters command allows you to give your running programs command-line arguments exactly as if you had typed
them on the DOS command line. DOS redirection commands will be ignored.

When you choose this command, a dialog box appears with a single input box.

Parameters take effect only when your program is started. If you are already debugging and wish to change the parameters, you can select Program Reset and then start the program with the new parameters.

Compile menu

Use the commands on the Compile menu to compile, make, or build the program in the active window. To use the Compile, Make, and Build commands, you must have a file open in an active Edit window. For example, if you open an Output or Watch window, those selections will be disabled.

Compile

The Compile | Compile command compiles the active editor file. When Turbo Pascal is compiling, a status box pops up to display the compilation progress and results. When compiling/linking is complete, press any key to remove this box. If any errors occur, the Edit window containing the offending source code becomes active, an error message is displayed, and the cursor is placed on the first error location.

Make

The Compile | Make command invokes the built-in project manager to make an .EXE file.

- If a Primary File has been named, that file is compiled; otherwise, the file in the active Edit window is compiled. Turbo Pascal checks all files upon which the file being compiled depends.
Build

Destination

Primary File

- If the source file for a given unit has been modified since the .TPU (object code) file was created, then that unit is recompiled.
- If the interface for a given unit has been changed, then all other units that depend upon it are recompiled.
- If a unit links in an .OBJ file (external routines), and the .OBJ file is newer than the unit's .TPU file, then the unit is recompiled.
- If a unit includes an Include file and the Include file is newer than that unit's .TPU file, then the unit is recompiled.

If the source to a unit (.TPU file) cannot be located, that unit is not compiled, but is used as is.

Compile | Make rebuilds only the files that aren't current and the one in the active Edit window (or Primary File if specified).

Build

The Compile | Build command rebuilds all the files regardless of whether they're out of date. This command is similar to Compile | Make except that it is unconditional.

Destination

The Compile | Destination command lets you specify whether the executable code will be stored on disk (as an .EXE file) or whether it will be stored in memory (and thus lost when you exit Turbo Pascal). Note that even if Destination is set to Memory, any units recompiled during a Make or Build have their .TPU files updated on disk.

If Destination is set to Disk, then an .EXE file is created and its name is derived from one of two names, in the following order: the Primary File name or, if none is specified, the name of the file in the active Edit window.

The resulting .EXE and .TPU (if any) is stored in the same directory as their respective source files, or in the EXE & TPU Directory (Options | Directories), if one is specified.

Primary File

Select the Primary File command to specify which .PAS file will get compiled when you use Compile | Make (F9) or Build (Alt-C B). You'll want to use this option when you're working on a program that uses several unit or Include files. No matter which file you've

Chapter 7, The IDE reference
been editing, Make or Build will always operate on your primary file. If you specify another file as a primary file, but want to compile only the file in the selected Edit window, choose Compile (Alt-F9).

### Debug menu

The commands on the Debug menu control all the features of the integrated debugger. You can change default settings for these commands in the Options | Debugger dialog box. For more about debugging, refer to Chapter 5, “Debugging Turbo Pascal programs.”

#### Evaluate/Modify

The Debug | Evaluate/Modify command evaluates a variable name or expression, displays its value, and, if appropriate, lets you modify the value. The command opens a dialog box containing the Expression, the Result, and the New Value fields.

The Expression field shows a default expression consisting of the word at the cursor in the Edit window. You can evaluate the default expression by pressing Enter, or you can edit or replace it first. You can also press → to extend the default expression by copying additional characters from the Edit window.

If the debugger can evaluate the expression, it displays the value in the Result field. If the expression refers to a variable or simple data element, you can move the cursor to the New Value field and enter an expression as the new value.

Press Esc to close the dialog box. If you’ve changed the contents of the New Value field but do not select Modify, the debugger will ignore the New Value field when you close the dialog box.
Use a repeat expression to display the values of consecutive data elements. For example, for an array of integers named `ListInt`,

- `ListInt[0],5` displays five consecutive integers in decimal.
- `ListInt[0],5x` displays five consecutive integers in hex.

An expression used with a repeat count must represent a single data element. The debugger views the data element as the first element of an array if it isn't a pointer, or as a pointer to an array if it is.

The **Debug | Evaluate/Modify** command displays each type of value in an appropriate format. For example, it displays an integer in base 10 (decimal), and an array as a pointer in base 16 (hexadecimal). To get a different display format, precede the expression with a comma followed by one of the format specifiers shown in Table 7.1.

### Table 7.1: Format specifiers recognized in debugger expressions

<table>
<thead>
<tr>
<th>Character</th>
<th>Function</th>
</tr>
</thead>
<tbody>
<tr>
<td>C</td>
<td><strong>Character</strong>. Shows special display characters for control characters (ASCII 0 through 31); by default, such characters are shown ASCII values using the #xx syntax. Affects characters and strings.</td>
</tr>
<tr>
<td>S</td>
<td><strong>String</strong>. Shows control characters (ASCII 0 through 31) as ASCII values using the #xx syntax. Since this is the default character and string display format, the S specifier is only useful in conjunction with the M specifier.</td>
</tr>
<tr>
<td>D</td>
<td><strong>Decimal</strong>. Shows all integer values in decimal. Affects simple integer expressions as well as structures (arrays and records) containing integers.</td>
</tr>
<tr>
<td>$, H, or X</td>
<td><strong>Hexadecimal</strong>. Shows all integer values in hexadecimal with the $ prefix. Affects simple integer expressions as well as structures (arrays and records) containing integers.</td>
</tr>
<tr>
<td>Fn</td>
<td><strong>Floating point</strong>. Shows n significant digits (n is an integer between 2 and 18). The default value is 11. Affects only floating-point values.</td>
</tr>
<tr>
<td>M</td>
<td><strong>Memory dump</strong>. Displays a memory dump, starting with the address of the indicated expression. The expression must be a construct that would be valid on the left side of an assignment statement, i.e., a construct that denotes a memory address; otherwise, the M specifier is ignored. By default, each byte of the variable is shown as two hex digits. Adding a D specifier with the M causes the bytes to be displayed in decimal. Adding an H, $, or X specifier causes the bytes to be displayed in hex with a $ prefix. An $ or a C specifier causes the variable to be displayed as a string (with or without special characters). The default number of bytes displayed corresponds to the size of the variable, but a repeat count can be used to specify an exact number of bytes.</td>
</tr>
<tr>
<td>P</td>
<td><strong>Pointer</strong>. Displays pointers in seg : ofs format rather than the default <code>Ptr(seg,ofs)</code> format. For example, displays <code>3EA0:0020</code> instead of <code>Ptr($3EA0,$20)</code>. Affects only pointer values.</td>
</tr>
<tr>
<td>R</td>
<td><strong>Record</strong>. Displays record and object field names such as <code>(X:1;Y:10;Z:5)</code> instead of `(1, 10, 5). Affects only record variables and objects with fields.</td>
</tr>
</tbody>
</table>
Watches

The Debug | Watches command opens a pop-up menu of commands that control the use of watchpoints. The following sections describe the commands in this pop-up menu.

Add Watch

The Add Watch command inserts a watch expression into the Watch window.

When you choose this command, the debugger opens a dialog box and prompts you to enter a watch expression. The default expression is the word at the cursor in the current Edit window. There's also a history list available if you want to watch an expression you've used before.

When you type a valid expression and press Enter or click OK, the debugger adds the expression and its current value to the Watch window. If the Watch window is the active window, you can insert a new watch expression by pressing Ins.

Delete Watch

While you're in the Watch window, you can select Delete Watch to delete the current watch expression from the Watch window, or press either Del or Ctrl-Y. The current watch expression is marked by a bullet in the left margin.

Edit Watch

The Edit Watch command allows you to edit the current watch expression in the Watch window. When you choose this command, you'll get a dialog box that contains a copy of the current watch expression. Edit the expression and then press Enter; this replaces the original expression with the edited one.

To edit a watch expression from inside the Watch window, select the expression and press Enter.

Remove All Watches

The Remove All Watches command deletes all watch expressions from the Watch window.

Toggle Breakpoint

The Debug | Toggle Breakpoint command lets you set or clear an unconditional breakpoint on the line where the cursor is positioned. When a breakpoint is set, it is marked by a breakpoint
Breakpoints

The **Debug | Breakpoints** command opens a dialog box that lets you control the use of breakpoints:

![Breakpoints dialog box](image)

The dialog box shows you all set breakpoints, their line numbers, and the conditions. The condition has a history list so you can select a breakpoint condition that you've used before.

Whenever your running program encounters a breakpoint, it will stop with a run bar positioned on the line with the breakpoint.

Before you compile a source file, you can set a breakpoint on any line, even a blank line or a comment. When you compile and run the file, Turbo Pascal validates any breakpoints that are set and gives you a chance to remove, ignore, or change invalid breakpoints. When you are debugging the file, Turbo Pascal knows which lines contain executable statements, and will warn you if you try to set invalid breakpoints.

You can remove breakpoints from your program by choosing the **Delete** button. You can also view the source where existing breakpoints are set by choosing the **View** button. View moves the cursor to the selected breakpoint in the Edit window (it does not run your code).

Choose **Edit** to add a new breakpoint to the list. When you edit a breakpoint, this dialog box pops up over the first one:

---

You can set an unconditional breakpoint by choosing **Debug | Toggle Breakpoint**.

This dialog box has no **Cancel** button, so edit and delete with care.
Again, line number and conditions are that of the breakpoints you've set. Use Pass Count to set how many times the breakpoint should be skipped before stopping.

When a source file is edited, each breakpoint "sticks" to the line where it is set. Breakpoints are lost only when:

- you delete the breakpoint in the Breakpoints dialog box
- you delete the source line a breakpoint is set on
- you clear a breakpoint with Toggle Breakpoint

Turbo Pascal will attempt to track breakpoints in two cases:

- If you edit a file containing breakpoints and then don't save the edited version of the file.
- If you edit a file containing breakpoints and then continue the current debugging session without remaking the program. (Turbo Pascal displays the warning prompt "Source modified, rebuild?")

This dialog box also has a New button, which lets you enter breakpoint information for a new breakpoint, and a Modify button, which accepts the settings of the box.

Options menu

The Options menu contains commands that let you view and change various default settings in Turbo Pascal. Most of the commands in this menu lead to dialog boxes.
Compiler

The Options | Compiler command displays a dialog box that lets you set several options that affect code compilation. Here’s what the dialog box looks like:

![Compiler Options dialog box](image)

The following sections describe these commands.

**Code Generation**

You can use the check boxes in the Code Generation group to tell the compiler to prepare your code in certain ways. Here are what the various buttons and check boxes mean:

- **Force Far Calls** allows you to force all procedures and functions to use the far call model. If the option is not enabled, the compiler will use the near call models for any procedures or functions within the file being compiled.

- **Overlays Allowed** enables or disables overlay code generation. Turbo Pascal allows a unit to be overlaid only if it was compiled with Overlays Allowed checked (set to on). In this state, the code generator takes special precautions passing string and set constant parameters from one overlaid procedure or function to another.

Checking the Overlays Allowed check box does not force you to overlay that unit. It instructs Turbo Pascal to ensure that the unit can be overlaid, if so desired. If you develop units that you plan to use in overlaid as well as non-overlaid applications, then compiling them with Overlays Allowed checked ensures that you can indeed do both with the same unit.
- **Word Align Data** (when checked) tells Turbo Pascal to align noncharacter data at even addresses. When this option is off (unchecked), Turbo Pascal uses byte-aligning, where data can be aligned at either odd or even addresses, depending on which is the next available address. (This is equivalent to the `$A` compiler directive.)

  Word alignment increases the speed with which 8086 and 80286 processors fetch and store the data.

- **286 Instructions** tells Turbo Pascal to generate code for the 80286 instruction set. Note that programs compiled with 80286 code generation turned on do not check for the presence of an 80286 at run time. (This is equivalent to the `$G` compiler directive.)

### Run-time Errors

The Run-time Errors group let you select which run-time errors are generated.

- When **Range Checking** is checked, the compiler generates code to check that array and string subscripts are within bounds, and that assignments to scalar-type variables don't exceed their defined ranges. If the check fails, the program halts with a run-time error. When unchecked, **Range Checking** is disabled. (This is equivalent to the `$R` compiler directive.)

- When **Stack Checking** is checked, the compiler generates code to check that space is available for local variables on the stack before each call to a procedure or function. If the check fails, the program halts with a run-time error. When unchecked, **Stack Checking** is disabled. (This is equivalent to the `$S` compiler directive.)

- When **I/O Checking** is checked, the compiler generates code to check for I/O errors after every I/O call. If the check fails, the program halts with a run-time error. When the option is unchecked, I/O Checking is disabled; however, the user can test for I/O errors via the system function `IOResult`. (I/O checking is equivalent to the `$I` compiler directive.)

### Syntax Options

This group lets you select the type of syntax options you want to search for.

- With the **Strict Var-Strings** option enabled, the compiler compares the declared type of a `var`-type string parameter with the type of the actual parameter being passed. If they are not identical, a compiler error occurs. With the option disabled, no
such type checking is done. (This option is equivalent to the $V compiler directive.)

- With Complete Boolean Evaluation enabled, all terms in a Boolean expression are always evaluated. If disabled, the compiler generates code to terminate evaluation of a Boolean expression as soon as possible; for example, in the expression if False and MyFunc..., the function MyFunc would never be called. (This option is equivalent to the $B compiler directive.)

- With the Extended Syntax option enabled, Turbo Pascal’s syntax is extended to let you use user-defined function calls as statements, as if they were procedures. When this option is disabled, this extension is disabled. Refer to Chapter 21 in the *Programmer’s Guide* for more information. (This option is equivalent to the $X directive.)

The Numeric Processing options let you decide how you want Turbo Pascal to handle floating-point numbers.

- Choose 8087/80287 to generate direct 8087 or 80287 inline code. This option is equivalent to the $N compiler directive.
- Choose Emulation if you want Turbo Pascal to detect whether your computer has an 80x87 coprocessor (and to use it if you do). If it is not present, Turbo Pascal emulates the 80x87. The $E compiler directive is equivalent to this option.

For more information about the compiler directive equivalents, refer to Chapter 21 in the *Programmer’s Guide*.

You can set the options in the Debugging group to turn on or off debug information or local symbol generation.

- Checking Debug Information enables the generation of debug information, which consists of a line-number table for each Pascal statement that maps object code addresses into source text numbers. (This is equivalent to the $D compiler directive.)

When you’ve checked Debug Information for a given program or unit, the IDE allows you to single-step and set breakpoints in that module. Also, when a run-time error occurs in a program or unit compiled with Debug Information checked, Turbo Pascal can automatically take you to the statement that caused the error with Search | Find Error.

For units, the debug information is recorded in the .TPU file, along with the unit’s object code. Debug information increases
the size of .TPU files, and takes up additional memory when programs compile that use the unit, but it doesn’t affect the size or speed of the executable program.

Those parts of your source code compiled and linked with Debug Information unchecked are not accessible to the debugger. If disk space is at a premium, uncheck Debug Information to create smaller .TPU files and use less memory during compilation and run time.

Checking Local Symbols enables the generation of local symbol information, which consists of the names and types of all local variables and constants in a module (the symbols in the module’s implementation part, and the symbols within the module’s procedures and functions). (Local Symbols is equivalent to the $L compiler directive.)

When you’ve checked Local Symbols for a given program or unit, the IDE allows you to examine and modify the module’s local variables. Also, calls to the module’s procedures and functions can be examined with the Window I Call Stack command.

For units, the local symbol information is recorded in the .TPU file along with the unit’s object code. Local symbol information increases the size of .TPU files and takes up additional room when you compile programs that use the unit, but it doesn’t affect the size or speed of the executable program.

Use the Conditional Defines input box to enter define symbols to be referenced in conditional compilation directives (refer to Chapter 21 in the Programmer’s Guide). You can separate multiple defines with semicolons (;), for example,

TestCode;DebugCode

The Memory Sizes options let you configure the default memory requirements for a program. All three settings can be specified in your source code using the $M compiler directive. If you attempt to run your program and there is not enough heap space to satisfy the specified requirement, the program aborts with a run-time error. (This is equivalent to the $M compiler directive.)

- Stack Size specifies the size (in bytes) of the stack segment. The default size is 16,384, the maximum size is 65,520.
You must specify a smaller limit if your program executes other programs. Refer to Exec in Chapter 1 of the Library Reference for more detail.

Low Heap Limit specifies the minimum required heap size (in bytes). The default minimum size is 0K.

High Heap Limit specifies the maximum amount of memory (in bytes) to allocate to the heap. The default is 655360, which (on most systems) will allocate all available memory to the heap. This value must be greater than or equal to the smallest heap size.

The Options | Linker command opens a dialog box that lets you make several settings that affect linking:

This dialog box has several radio buttons, which are described in the following sections.

Use the Map File radio buttons to choose the type of map file to be produced. For settings other than Off, the map file is placed in the EXE and TPU directory defined in the Options | Directories dialog box. The default setting for the map file is off. (Segments, Publics, and Detailed are equivalent to the /GS, /GP, and /GD command-line options.)

The Link Buffer option tells Turbo Pascal to use Memory or Disk for the link buffer. When you select the Memory radio button, it speeds compilation, but you may run out of memory for large programs. Selecting the Disk radio button frees up memory, but slows compilation. (This is equivalent to the /L command-line option in TPC.EXE.)

The Options | Debugger command opens a dialog box that lets you make several settings affecting the integrated debugger:
The following sections describe the contents of this box.

The Debugging check boxes determine whether debugging information is included in the executable file and how the .EXE is run under Turbo Pascal.

- Choose Integrated (the default) to debug programs with the integrated debugger or the standalone Turbo Debugger.
- Choose Standalone to debug programs with Turbo Debugger.

The Integrated, Standalone (Options | Debugger), and Map File options (Options | Linker) produce complete and local symbol information for a module only if you've compiled that module with Debug Information and Local Symbols checked, respectively.

The Display Swapping radio buttons let you set when the integrated debugger will change display windows while running a program.

If you're debugging in dual monitor mode (used the Turbo Pascal command-line /d option), you can see your program's output on one monitor and the Turbo Pascal screen on the other. In this case, Turbo Pascal never swaps screens and the Display Swapping setting has no effect.

- If you set Display Swapping to None, the debugger does not swap the screen at all. You should only use this setting for debugging sections of code that you're certain do not output to the screen.
- When you run your program in debug mode with the default setting of Smart, the debugger looks at the code being executed to see whether it will generate output to the screen. If the code does output to the screen (or if it calls a procedure), the screen is swapped from the IDE screen to the User screen long enough for output to be displayed, then is swapped back. Otherwise, no swapping occurs. Be aware of the following with smart swapping:
- It swaps on any procedure call, even if the procedure does no
  screen output.
- In some situations, the IDE screen might be modified without
  being swapped; for example, if a timer interrupt routine
  writes to the screen.

 **If you set Display Swapping to Always, the debugger swaps
 screens every time a statement executes. You should choose this
 setting any time the IDE screen is likely to be overwritten by
 your running program.**

---

### Directories

The **Options | Directories** command lets you tell Turbo Pascal
where to find the files it needs to compile, link, and output files.

This command opens a dialog box containing four input boxes. The
dialog box looks like this:

![Directories dialog box](image)

Use the following guidelines when entering directories in these
input boxes:

- You must separate multiple directory path names (if allowed)
  with a semicolon (;). You can use up to a maximum of 127
  characters (including whitespace).
- Whitespace before and after the semicolon is allowed but not
  required.
- Relative and absolute path names are allowed, including path
  names relative to the logged position in drives other than the
  current one. For example,

  `C:\PASCAL;C:\PASCAL\MYPROJS;A:TURBO\EXAMPLES;`

Here is a description of each input box.

- Enter the output directory for .EXE or .TPU files in the **EXE and
  TPU directory** input box. If the entry is blank, the files are
  stored in the directory where the source is found. .MAP files are
also stored here if Map File (Options | Linker) is set to anything besides Off.

- Use the Include Directories input box to specify the directories that contain your standard Include files. Include files are those specified with the \$I [filename] compiler directive. Multiple directories are separated by semicolons (;), as in the DOS PATH command.

- Use the Unit Directories input box to specify the directories that contain your Turbo Pascal unit files. Multiple directories are separated by semicolons (;), as in the DOS PATH command. To use the Graph unit, for example, you could create a directory \TURBO\BGI, copy GRAPH.TPU and specify a unit directory of \TURBO\BGI. If you also wanted to keep other units in a \TURBO\UNITS directory, your unit directory would be \TURBO\UNITS; \TURBO\BGI.

- Use the Object Directory input box to specify the directories that contain .OBJ files (assembly language routines). When Turbo Pascal encounters a \$L [filename] directive, it looks first in the current directory, then in the directories specified here. Multiple directories are separated by semicolons (;), as in the DOS PATH command.

Environment

The Options | Environment command lets you make environment-wide settings. This command opens a menu that lets you choose settings from Preferences, Editor, and Mouse.

Preferences

Here's what the Preferences dialog box looks like:

- The Screen Sizes radio buttons let you specify whether your IDE screen is displayed in 25 or 43/50 lines. One or both of these buttons will be available, depending on the type of video adapter in your PC.
When set to 25 lines (the default), Turbo Pascal uses 25 lines and 80 columns. This is the only screen size available to systems with a monochrome display or Color Graphics Adapter (CGA). If your PC has EGA or VGA, you can set this option to 43/50 lines. The IDE is displayed in 43 lines by 80 columns if you have an EGA, or 50 lines by 80 columns if you have a VGA.

When stepping source or locating an error position in your source code, the IDE opens a new window whenever it encounters a file that is not already loaded. Selecting **Current Window** causes the IDE to replace the contents of the topmost Edit window with the new file instead of opening a new Edit window.

If Editor Files is checked in the Auto Save options, and if the file has been modified since the last time you saved it, Turbo Pascal automatically saves the source file in the Edit window whenever you choose the **Run** | **Run** (or any debug/run command) or **File** | **DOS Shell** command.

When the **Environment** option is checked, all the settings you made in this session will be saved automatically into a TURBO.TP configuration file when you exit Turbo Pascal.

When **Desktop** is checked, Turbo Pascal controls whether your desktop (in the file TURBO.DSK) is saved on exit and whether it's restored when you return to Turbo Pascal. Your desktop information will not be saved unless a .TP file is created (automatically or manually by selecting the **Options** | **Save Options** command) and the **Desktop** radio button is set to something other than **None**.

If you want the IDE to use a desktop file to save and restore your desktop from one programming session to another, select either the Current Directory or Config File Directory radio button. When the IDE saves a TURBO.TP configuration file, it will also create a TURBO.DSK file that contains edit window information, the positions of all windows on the desktop, history lists, breakpoint locations, and other state information. All this can be saved and restored automatically by enabling both the **Environment** and **Desktop** options in the Auto Save group. Alternatively, you can create a TURBO.TP manually by using the **Options** | **Save Options** dialog box.

When you next load TURBO.EXE, it will look for TURBO.TP and TURBO.DSK in the current directory. When located, they are loaded and the previous session's configuration and
desktop states are restored. If no TURBO.TP is found in the current directory, the IDE also will look for it in the directory that contains TURBO.EXE itself.

Editor

If you choose Editor from the Environment menu, the Editor Options dialog box has several check boxes that control how Turbo Pascal handles text in Edit windows.

- When Create Backup Files is checked (the default), Turbo Pascal automatically creates a backup of the source file in the Edit window when you choose File | Save and gives the backup file the extension .BAK.
- When Insert Mode is not checked, any text you type into Edit windows overwrites existing text. When the option is checked, text you type is inserted (pushed to the right). Pressing Ins toggles Insert mode when you’re working in an Edit window.
- When Autoindent Mode is checked, pressing Enter in an Edit window positions the cursor under the first nonblank character in the preceding nonblank line. This can be a great aid in keeping your program code more readable.
- When Autoindent Mode is checked, pressing Enter in an Edit window positions the cursor under the first nonblank character in the preceding nonblank line. This can be a great aid in keeping your program code more readable.
- When Use Tab Character is checked, Turbo Pascal inserts a true tab character (ASCII 9) when you press Tab. When this option is not checked, Turbo Pascal replaces tabs with spaces, the number of which is determined by the Tab Size setting.
- When you check Optimal Fill, Turbo Pascal begins every autoindented line with the minimum number of characters possible, using tabs and spaces as necessary. This produces lines with fewer characters than when Optimal Fill is not checked.
- When Backspace Unindents is checked (the default) and the cursor is on a blank line or the first non-blank character of a line, the Backspace key aligns (outdents) the line to the previous indentation level.
- When you check Cursor Through Tabs, the arrow keys will move the cursor to the middle of tabs; otherwise the cursor jumps several columns when cursoring over a tab.
- If you check Use Tab Character in this dialog box and press Tab, Turbo Pascal inserts a tab character in the file and the cursor moves to the next tab stop. The Tab Size input box allows you to dictate how many characters to move for each tab stop. Legal values are 2 through 16; the default is 8.
To change the way tabs are displayed in a file, just change the tab size value to the size you prefer. Turbo Pascal redisplay all tabs in that file in the size you chose. You can save this new tab size in your configuration file by choosing Options | Save Options.

Mouse

When you choose Mouse from the Environment menu, the Mouse Options dialog box is displayed, which contains all the settings for your mouse.

The Right Mouse Button radio buttons determine the effect of pressing the right button of the mouse (or the left button, if the Reverse mouse buttons option is checked). Topic Search is the default.

Here's a list of what the right button would do if you choose something other than Nothing:

- Topic Search:
  - Same as Help | Topic Search
  - Same as Run | Go To Cursor
  - Same as Debug | Toggle Breakpoint
  - Same as Debug | Evaluate
  - Same as Debug | Watches | Add Watch

In the Mouse Double Click box, you can change the slider control bar to adjust the double-click speed of your mouse by using the arrow keys.

Moving the scroll box closer to Fast means Turbo Pascal requires a shorter time between clicks to recognize a double click. Moving the scroll box closer to Slow means Turbo Pascal will still recognize a double click even if you wait longer between clicks.

When Reverse Mouse Buttons is checked, the active button on your mouse is the rightmost one instead of the leftmost. Note, however, that the buttons won't actually be switched until you choose the OK button.

Startup

Choosing Startup from the Environment menu lets you select settings for the integrated environment.
All of these options correspond to the command-line options mentioned at the beginning of this chapter (see page 174).

The changes that you make here are written directly to TURBO.EXE and don’t take affect until the next time you load the IDE.

Colors

Use the Colors dialog box to customize the IDE for your use.

The Group list contains the names of the different regions of the IDE that can be customized. When you select a group, the Item list box will contain the names of the different views in that region. On color and black and white systems, you can modify the foreground and background colors by using your mouse or cursor keys to change the palette. On all systems, the text in the lower right corner of the dialog box reflects the current settings. Changes do not take affect on the desktop until you close the dialog box (by selecting OK).
Save Options

Save your desktop state (TURBO.DSK) by setting Desktop to Current Directory or Config File Directory in the Preferences dialog box.

The Options | Save Options command brings up a dialog box that lets you save settings that you’ve made in both the Find and Replace dialog boxes (off the Search menu), the Destination and Primary File options (off the Compile menu) and all the settings under the Options menu. All options and the editor command table are stored in TURBO.TP; history lists, your desktop state, and breakpoint locations are stored in TURBO.DSK.

If it doesn’t find the files, Turbo Pascal looks for these files’ directory where TURBO.EXE is run from.

Retrieve Options

The Options | Retrieve Options command brings up a dialog box that lets you retrieve the settings that you’ve made in both the Find and Replace dialog boxes (off the Search menu), the Destination and Primary File options (off the Compile menu) and all the settings under the Options menu. If the Desktop file (.DSK) is set to either Current Directory or Config File Directory, TURBO.DSK will also be loaded.

Window menu

Refer to page 11 for information on window elements and how to use them.

The Window menu contains window management commands. Most of the windows you open from this menu have all the standard window elements like scroll bars, a close box, and zoom boxes.

The commands Tile and Cascade will always rearrange Edit windows in the region above a Watch, Output, or Call Stack window. If none of these windows are open, Tile and Cascade will use the entire desktop.

At the bottom of the Window menu, the Window | List command appears. Choose this command for a list of all open windows.
Size/Move

Choose Window | Size/Move to change the size or position of the active window. When you choose this command, the active window moves in response to the arrow keys. When the window is where you want it, press Enter. You can also move a window by dragging its title bar.

If you press Shift while you use the arrow keys, you can change the size of the window. When the window is the size you want it, press Enter. If a window has a resize corner, you can drag that corner or any other corner to resize it.

Zoom

Choose Window | Zoom to resize the active window to the maximum size. If the window is already zoomed to the maximum, you can choose this command again to restore it to its previous size. You can also double-click anywhere on the top line (except where an icon appears) of a window to zoom or unzoom it.

Tile

Choose Window | Tile to view equally all your open Edit windows. Tiling makes all your open Edit windows a similar size and lays them out one next to the other so none overlap.

Cascade

Choose Window | Cascade to stack all open Edit windows. Cascade only lets you fully view the active window; only file names and window numbers are visible for the other windows.

Next

Choose Window | Next to make the next window active, which makes it the topmost open window.

Previous

Choose Window | Previous to make the previous window active (the window last opened before the currently active one).
### Close

Choose Window | Close to close the active window. You can also click the close box in the upper left corner to close a window.

### Watch

Choose Window | Watch to open the Watch window and make it active. The Watch window displays expressions and their changing values so you can keep an eye on how your program evaluates key values.

You use the commands in the Debug | Watches pop-up menu to add or remove watches from this window. Refer to the section on this menu for information on how to use the Watch window (page 196).

To close the window, click its close box or choose Window | Close.

### Register

Choose Window | Register to open the Register window and make it active. The Register window displays CPU registers and is especially useful when debugging inline assembler. To close the window, click its close box or choose Window | Close.

### Output

Choose Window | Output to open the Output window and make it active. The Output window displays text from any DOS command-line text and any text generated from your program (no graphics).

The Output window is handy while debugging because you can view your source code, variables, and output all at once. This is especially useful when you've set the Options | Environment dialog box to a 43-line display and you are running a standard 25-line mode program. In that case, you can see almost all of the program output and still have plenty of lines to view your source code and variables.

If you would rather see your program's text on the full screen—or if your program generates graphics—choose the Window | User Screen command instead (Alt-F5).
To close the window, click its close box or choose Window | Close.

**Call Stack**

The Window | Call Stack command opens a window that shows the sequence of procedures your program called to reach the procedure currently running. At the bottom of the stack is Program (or your program name); at the top is the procedure that’s currently running.

Each entry on the stack displays the name of the procedure called and the values of the parameters passed to it.

Initially the entry at the top of the stack is highlighted. To display the current line of any other procedure on the call stack, select that procedure’s name and press Enter. The cursor moves to the line containing the call to the procedure next above it on the stack. The call stack will stay on the desktop until you close it.

**User Screen**

Choose Window | User Screen to view your program’s full-screen output. If you would rather see your program output in a Turbo Pascal window, choose the Window | Output command instead. Clicking or pressing any key returns you to the integrated environment.

**List**

Choose Window | List to get a list of all the windows you’ve opened; the list contains the names of all files that are currently open. When you make a selection from the list, Turbo Pascal brings the window to the front and makes it active.

Press Alt-0 to pop up a complete list of all open windows. For a full rundown of how to manage windows, see page 13.

**Help menu**

The Help menu gives you access to online help in a special window. There is help information on virtually all aspects of the IDE and Turbo Pascal. (Also, one-line menu and dialog box hints appear on the status line whenever you select a command.)
To open the Help window, do one of these actions:

- Press F1 at any time (including from any dialog box or when any menu command is selected).
- When an Edit window is active and the cursor is positioned on a word, press Ctrl-F1 to get language help.
- Click Help whenever it appears on the status line or in a dialog box.

To close the Help window, press Esc, click the close box, or choose Window | Close. You can keep the Help window onscreen while you work in another window unless you opened the Help window from a dialog box or pressed F1 when a menu command was selected. (If you press F6 or click on another window while you’re in Help, the Help window remains onscreen.)

Help screens often contain keywords (highlighted text) that you can choose to get more information. Press Tab to move to any keyword; press Enter to get more detailed help. (As an alternative, move the cursor to the highlighted keyword and press Enter. With a mouse, you can double-click any keyword to open the help text for that item.

You can also cursor around the Help screen and press Ctrl-F1 on any word to get help. If the word is not found, an incremental search is done in the index and the closest match displayed.

When the Help window is active, you can copy from the window and paste that text into an Edit window. You do this just the same as you would in an Edit window: Select the text first (using Shift→, Left arrow, Up arrow, Down arrow), choose Edit | Copy, move to an Edit window, then choose Edit | Paste.

To select text in the Help window, drag across the desired text or, when positioned at the start of the block, press Shift→, ←, ↑, ↓ to mark a block.

You can also copy preselected program examples from help screens by choosing the Edit | Copy Example command.

The Help | Contents command opens the Help window with the main table of contents displayed. From this window, you can branch to any other part of the help system.
You can get help on Help by pressing F1 when the Help window is active. You can also reach this screen by clicking on the status line.

The Help | Index command opens a dialog box displaying a full list of help keywords (the special highlighted text in help screens that let you quickly move to a related screen).

You can scroll the list or you can incrementally search it by pressing letters from the keyboard. For example, to see what's available under "printing," you can type p r i. When you type p, the cursor jumps to the first keyword that starts with p. When you then type r, the cursor then moves to the first keyword that starts with pr. When you then type i, the cursor moves to the first keyword that starts with pri, and so on.

When you find a keyword that interests you, choose it by cursoring to it and pressing Enter. (You can also double-click it.)

The Help | Topic Search command displays language help on the currently selected item.

To get language help, position the cursor on an item in an Edit window and choose Topic Search. You can get help on things like procedure names (Writeln, for example), reserved words, and so on. If an item is not in the help system, the help index displays the closest match.

The Help | Previous Topic command opens the Help window and redisplays the text you last viewed.

Turbo Pascal lets you back up through 20 previous help screens. You can also click on the status line to view the last help screen displayed.
The Help | Help on Help command opens up a text screen that explains how to use the Turbo Pascal help system. If you’re already in help, you can bring up this screen by pressing F1.
The editor from A to Z

This chapter is a reference to Turbo Pascal’s full range of editing commands. Table 8.1 contains a list of all of the editor commands; the tables and text that follow it cover those aspects of the editor that need further explanation.

Remember, this chapter is concerned just with the editor. For a tutorial about the editor and the IDE, refer to Chapter 1; for an in-depth discussion of the whole Turbo Pascal integrated environment, refer to Chapter 7.

The new and the old

The new Turbo Pascal IDE still lets you use Borland’s familiar hot key combinations to move around your file, insert, copy, and delete text, and search and replace. However, it also provides you with two brand-new menus on the menu bar, the Edit menu and the Search menu. In addition, Turbo Pascal now supports use of a mouse for many of the cursor movement and block-marking commands.

The Edit menu contains commands for cutting, copying, and pasting in a file, copying examples from Help to an Edit window, and viewing the Clipboard. When you first start Turbo Pascal, an Edit window is already active. To open other Edit windows, go to the File menu and choose Open. From an Edit window, you still press F10 to get to the menu bar; to return to the Edit window,
keep pressing Esc until you are out of the menus. If you have a mouse, you can also just click anywhere in the Edit window.

As always, you enter text pretty much as if you were using a typewriter. To end a line, press Enter. When you've entered enough lines to fill the screen, the top line scrolls off the screen. Don't worry—it isn't lost; you can move back and forth in your text with the scrolling commands that are described later.

The editor has a restore facility that lets you take back changes to the last line modified. This command (Edit | Restore line) is described on page 224 in the section titled "Other editing commands."

Editor reference

Table 8.1 summarizes all editor commands.

The editor is much more powerful than a quick tutorial can show. In addition to the menu choices, it uses approximately 50 commands to move the cursor around, page through text, find and replace strings, and so on. These commands can be grouped into four main categories:

- Cursor movement
- Insert and delete operations
- Block operations
- Miscellaneous editing operations

Most of these commands need no explanation. Those that do are described in the text following Table 8.1.

A word is defined as a sequence of characters separated by one of the following: space < > , ; . () ] ^ * + - / $ # _ = ~ ! " % & ' ; @ \, and all control and graphic characters.
Many of the commands in this table can also be performed with the mouse. See Chapter 7.

*This command opens the Editor Options dialog box, in which you can set the appropriate check box or radio buttons.

**Enter control characters by first pressing Ctrl-P, then pressing the desired control character. Depending on your screen setup, control characters appear as low-intensity or inverse capital letters.

***n represents a number from 0 to 9.

Jumping around

There are three cursor movement commands that need further explanation: Ctrl-Q B (Beginning of block), Ctrl-Q K (End of block), and Ctrl-Q P (Last cursor position).

Ctrl-Q B and Ctrl-Q K move the cursor to the block-begin or block-end marker. Both these commands work even if the block is not displayed (see “Hide/display block” in Table 8.2). Ctrl-Q B works even if the block-end marker is not set, and Ctrl-Q K works even if the block-begin marker is not set.

Ctrl-Q P moves to the last position of the cursor before the last command. This command is particularly useful after a search or search-and-replace operation has been executed, and you’d like to return to where you were at before you ran the search.

Block commands

A block of text is any amount of text, from a single character to hundreds of lines, that has been surrounded with special block-marker characters. There can be only one block in a window at a time. A block is marked by placing a block-begin marker on the first character and a block-end marker after the last character of
the desired portion of the text. Once marked, the block can be copied, moved, deleted, printed, or written to a file.

The search string is also called the target string.

The search string can contain any characters, including control characters. You can enter control characters with the Ctrl-P prefix. For example, search for a Ctrl-T by holding down the Ctrl key as you press P and then T. You can include a line break in a search string by specifying Ctrl-M (carriage return). (For searching regular expressions, take a look at the online file UTILS.DOC.)

The following sections list the steps for performing these operations.

1. Choose Search | Find. This opens the Find dialog box.
2. Type the string you are looking for into the Text to Find input box.
3. You can also set various search options:
   - The Direction radio buttons control whether you do a forward or backward search.
   - The Scope radio buttons control how much of the file you search.
   - The Origin radio buttons control where the search begins.
   - The Options check boxes determine whether the search will be case sensitive for whole words only, and for regular expressions.
   Use Tab or your mouse to cycle through the options. Use ↑ and ↓ to set the radio buttons and Space to toggle the check boxes.
4. Finally, choose the OK button to carry out the search or the Cancel button to cancel. Turbo Pascal performs the operation.
5. If you want to search for the same item repeatedly, use Search | Search Again.

1. Choose Search | Replace. This opens the Replace dialog box.
2. Type the string you are looking for into the Text to Find input box.
3. Press Tab or use your mouse to move to the New text input box. Type in the replacement string.
4. You can then set the same search options as in the Find dialog box.
5. Finally, choose OK or Change all to begin the search, or choose Cancel to cancel. Turbo Pascal performs the operation. Choosing Change all will replace every occurrence found.
6. If you want to stop the operation, press Esc at any point when the search has paused.

Pair matching

There you are, debugging your source file that is full of functions, parenthesized expressions, nested comments, and a whole slew of other constructs that use delimiter pairs. In fact, your file is riddled with

- braces: { and }
- parentheses: ( and )
- brackets: [ and ]
- double quotes: "
- single quotes: '

Finding the match to a particular paired construct can be tricky. Suppose you have a complicated expression with a number of nested expressions, and you want to make sure all the parentheses are properly balanced. Or say you're at the beginning of a function that stretches over several screens, and you want to jump to the end of that function. With Turbo Pascal's handy pair-matching commands, the solution is at your fingertips. Here's what you do:

1. Place the cursor on the delimiter in question.
2. To locate the mate to this selected delimiter, simply press Ctrl-Q.
3. The editor immediately moves the cursor to the delimiter that matches the one you selected. If it moves to the one you had intended to be the mate, you know that the intervening code contains no unmatched delimiters of that type. If it moves to the wrong delimiter, you know there's trouble; now all you need to do is track down the source of the problem.

We've told you the basics of Turbo Pascal's "Match Pair" commands; now you need some details about what you can and can't
do with these commands, and notes about a few subtleties to keep in mind. This section covers the following points:

- There are actually two match pair editing commands: one for forward matching (Ctrl-Q [) and the other for backward matching (Ctrl-Q ]).
- If there is no mate for the delimiter you’ve selected, the editor doesn’t move the cursor.

Two match pair commands are necessary because some delimiters are nondirectional.

For example, suppose you tell the editor to find the match for an opening brace ( { ) or an opening bracket ( [ ). The editor knows the matching delimiter can’t be located before the one you’ve selected, so it searches forward for a match. If you tell the editor to find the mate to a closing brace ( } ) or a closing parenthesis ( ) ), it knows that the mate can’t be located after the selected delimiter, so it automatically searches backward for a match.

However, if you tell the editor to find the match for a double quote ( " ) or a single quote ( ’ ), it doesn’t know automatically which way to go. You must specify the search direction by giving the correct match pair command. If you give the command Ctrl-Q Ctrl-[, the editor searches forward for the match; if you give the command Ctrl-Q Ctrl-], it searches backward for the match.

The following table summarizes the delimiter pairs, whether they imply search direction, and whether they are nestable:

<table>
<thead>
<tr>
<th>Delimiter pair</th>
<th>Direction implied?</th>
<th>Are they nestable?</th>
</tr>
</thead>

</tr>
</tbody>
</table>

**Nestable delimiters**

_Nestable_ means that, when the editor is searching for the mate to a directional delimiter, it keeps track of how many delimiter levels it enters and exits during the search.

This is best illustrated with some examples:

The command-line compiler

Turbo Pascal's command-line compiler (TPC.EXE) lets you invoke all the functions of the IDE compiler (TURBO.EXE) from the DOS command line. You can run the command-line compiler in either real or protected mode; both TPC and TPCX generate real mode programs only. The protected mode compiler (TPCX.EXE) lets you use extended memory to compile very large programs; it uses the same options as TPC.EXE.

You run TPC.EXE from the DOS prompt using a command line with the following syntax:

```
TPC [options] files
```

*options* are zero or more optional parameters that provide additional information to the compiler. *files* are the names of the sources file to compile. If you type TPC alone, it displays a help screen of command-line options and syntax.

If *files* does not have an extension, TPC assumes .PAS. If you don't want the file you're compiling to have an extension, you must append a period (.) to the end of *files*. If the source text contained in *files* is a program, TPC creates an executable file named FILENAME.EXE. If *files* contains a unit, TPC creates a Turbo Pascal unit file named FILENAME.TPU.

You can get help at the command line using THHELP; see THHELP.DOC in ONLINE.ZIP on your disk.

You can specify a number of options for TPC. An option consists of a slash (/) immediately followed by an option letter. In some cases, the option letter is followed by additional information, such
as a number, a symbol, or a directory name. Options can be given in any order and can come before and/or after the file name.

Compiler options

The IDE allows you to set various options through the menus; TPC gives you access to most of these same options using the slash (/) command. You can also precede options with a hyphen (-) instead of a slash (/), but those options that start with a hyphen must be separated by blanks. For example, the following two command lines are equivalent and legal:

TPC -IC:\TP\TVISION -DDEBUG SORTNAME -$S- -$F+
TPC /IC:\TP\TVISION/DDEBUG SORTNAME /$S-/ $F+

The first uses hyphens with at least one blank separating options; the second uses slashes and no separation is needed.

Table 9.1 lists all the command-line options and gives their integrated environment equivalents. In some cases, a single command-line option corresponds to two or three menu commands.

Turbo Pascal supports several compiler directives, all of which are described in Chapter 21 of the Programmer's Guide, "Compiler directives." When embedded in the source code, these directives take one of the following forms:

\[
\{$\text{directive+}\} \\
\{$\text{directive-}\} \\
\{$\text{directive info}\}
\]

The \$/S and \$/D command-line options allow you to change the default states of most compiler directives. Using \$/S and \$/D on the command line is equivalent to inserting the corresponding compiler directive at the beginning of each source file compiled.

The switch directive option

The \$/S option allows you to change the default state of the following switch directives: \$/A, \$/B, \$/D, \$/E, \$/F, \$/G, \$/I, \$/L, \$/N, \$/O, \$/R, \$/S, \$/V, and \$/X. The syntax of a switch directive option is \$/S.
followed by the directive letter, followed by a plus (+) or a minus (-). For example,

\texttt{TPC MYSTUFF /$R-}

would compile MYSTUFF.PAS with range checking turned off, while

\texttt{TPC MYSTUFF /$R+}

would compile it with range-checking turned on. Note that if a \texttt{$(R+) or $(R-) compiler directive appears in the source text, it overrides the \texttt{/$R} command-line option.

You can repeat the \texttt{/$} option in order to specify multiple compiler directives:

\texttt{TPC MYSTUFF /$R-/$/I-/$/V-/$/F+}

Alternately, TPC allows you to write a list of directives (except for \texttt{$M$}, separated by commas:

\texttt{TPC MYSTUFF /$R-,I-,V-,F+}

In addition to changing switch directives, \texttt{/$} also allows you to specify a program's memory allocation parameters, using the following format:

\texttt{/$MSTACK,HEAPMIN,HEAPMAX}

where \texttt{stack} is the stack size, \texttt{heapmin} is the minimum heap size, and \texttt{heapmax} is the maximum heap size. All three values are in bytes, and each is a decimal number unless it is preceded by a dollar sign ($), in which case it is assumed to be hexadecimal. So, for example, the following command lines are equivalent:

\texttt{TPC MYSTUFF /$M16384,O,655360}
\texttt{TPC MYSTUFF /$M$4000,$O,$AO000}

Note that, because of its format, you cannot use the \texttt{$M$ option in a list of directives separated by commas.

The conditional defines option

The \texttt{/D} option lets you define conditional symbols, corresponding to the \texttt{[$DEFINE symbol] compiler directive or the $O/C Conditional Defines option in the IDE. The \texttt{/D} option must be followed by one or more conditional symbols, separated by semicolons (;). For example, the following command line
defines three conditional symbols, _iocheck_, _debug_, and _list_, for the compilation of MYSTUFF.PAS. This is equivalent to inserting

```plaintext
{DEFINE IOCHECK}
{DEFINE DEBUG}
{DEFINE LIST}
```

at the beginning of MYSTUFF.PAS. If you specify multiple /D directives, you can concatenate the symbol lists are concatenated. Thus

```
TPC MYSTUFF /DIOCHECK/DDEBUG/DLIST
```

is equivalent to the first example.

## Compiler mode options

A few options affect how the compiler itself functions. These are

- `/M` (Make), `/B` (Build), `/F` (Find Error), `/L` (Link Buffer) and `/Q` (Quiet). As with the other options, you can use the hyphen format (remember to separate the options with at least one blank).

### The make (/M) option

TPC has a built-in MAKE utility to aid in project maintenance. The `/M` option instructs TPC to check all units upon which the file being compiled depends.

A unit will be recompiled if

- the source file for that unit has been modified since the .TPU file was created, or
- any file included with the $I directive, or any .OBJ file linked in by the $L directive, is newer than the unit's .TPU file, or
- the interface section of a unit referenced in a uses statement has changed

Units in TURBO.TPL are excluded from this process.

If you were applying this option to the previous example, the command would be

```
TPC MYSTUFF /M
```
The build all (/B) option

You can't use /M and /B at the same time.

Instead of relying on the /M option to determine what needs to be updated, you can tell TPC to update all units upon which your program depends using the /B option. This is the same as Compile | Build.

If you were using this option in the previous example, the command would be

```
TPC MYSTUFF /B
```

The find error option

This is the same as Find Error on the Search menu.

When a program terminates due to a run-time error, it displays an error code and the address (seg:ofs) at which the error occurred. By specifying that address in a /Fseg:ofs option, you can locate the statement in the source text that caused the error, provided your program and units were compiled with debug information enabled (via the $D compiler directive).

Suppose you have a file called TEST.PAS that contains the following program:

```pascal
program Test;
var
    i : integer;
begin
    i := 0;
    i := i div i;  { Force a divide by zero error }
end.
```

First, compile this program using the command-line compiler:

```
TPC TEST
```

If you do a DIR TEST.*, DOS lists two files: TEST.PAS, your source code, and TEST.EXE, the executable file.

Now, run TEST and you'll get a run-time error:

```
C:\>TEST
Run-time error 200 at 0000:0018
```

Notice that you're given an error code (200) and the address (0000:0018 in hex) of the instruction pointer (CS:IP) where the error occurred. To figure out which line in your source caused the
error, simply invoke the compiler, use /F and specify the segment and offset as reported in the error message:

C: \>TPC TEST /F0:18
Turbo Pascal Version 6.0 Copyright (c) 1983,90 Borland International
TEST.PAS (7)
TEST.PAS (6): Target address found.
i := i div i;

In order for TPC to find the run-time error with /F, you must compile the program with all the same command-line parameters you used the first time you compiled it.

The compiler now gives you the file name and line number, and points to the offending line number and text in your source code.

As mentioned previously, you must compile your program and units with debug information enabled for TPC to be able to find run-time errors. By default, all programs and units are compiled with debug information enabled, but if you turn it off, using a {$D-} compiler directive or a /$D- option, TPC will not be able to locate run-time errors.

The link buffer option

The /L option disables buffering in memory when .TPU files are linked to create an .EXE file. Turbo Pascal's built-in linker makes two passes. In the first pass through the .TPU files, the linker marks every procedure that gets called by other procedures. In the second pass, it generates an .EXE file by extracting the marked procedures from the .TPU files. By default, the .TPU files are kept in memory between the two passes; however, if the /L option is specified, they are reread during the second pass. The default method is faster but requires more memory; for very large programs, you may have to specify /L to link successfully.

The quiet option

The quiet mode option suppresses the printing of file names and line numbers during compilation. When TPC is invoked with the quiet mode option

TPC MYSTUFF /Q
its output is limited to the sign-on message and the usual statistics at the end of compilation. If an error occurs, it will be reported.

Directory options

TPC supports several options that allow you to specify the five directory lists used by TPC: Turbo, EXE & TPU, Include, Unit, and Object.

The EXE & TPU directory option

This option lets you tell TPC where to put the .EXE and .TPU files it creates. It takes a directory path as its argument:

\[ \text{TPC MYSTUFF /EC:TP\BIN} \]

If no such option is given, TPC creates the .EXE and .TPU files in the same directories as their corresponding source files.

The include directories option

Turbo Pascal supports include files through the \$I filename compiler directive. The /I option lets you specify a list of directories in which to search for Include files. Multiple directories are separated with semicolons (;). For example, the following command line causes TPC to search for include files in C:\TP\INCLUDE and D:\INC after searching the current directory:

\[ \text{TPC MYSTUFF /IC:TP\INCLUDE;D:\INC} \]

If multiple /I directives are specified, the directory lists can be concatenated. Thus

\[ \text{TPC MYSTUFF /IC:TP\INCLUDE/ID:\INC} \]

is equivalent to the first example.

The unit directories option

When you compile a program that uses units, TPC first attempts to find the units in TURBO.TPL (which is loaded along with TPC.EXE). If they cannot be found there, TPC searches for unitname.TPU in the current directory. The /U option lets you specify additional directories in which to search for units. As with
This is the same as the \texttt{OLDI} Unit Directories command.

the previous options, you can specify multiple directory paths as long as you separate them with semicolons (;). For example, the following command line causes TPC to look in C:\TP\UNITS and C:\LIBRARY for any units it doesn’t find in TURBO.TPL or the current directory:

\texttt{TPC MYSTUFF /UC:\TP\UNITS;C:\LIBRARY}

As with the \texttt{I} option, if multiple \texttt{U} options are specified, the directory lists can be concatenated.

This is the same as the \texttt{OLDI} Object Directories command.

The object files directories option

Using \texttt{($L \textit{filename})} compiler directives, Turbo Pascal allows you to link in .OBJ files containing external assembly language routines, as explained in Chapter 22, “The inline assembler,” in the Programmer’s Guide. The \texttt{O} option lets you specify a list of directories in which to search for such .OBJ files. Multiple directories are separated with semicolons (;). For example, the following command line causes TPC to search for .OBJ files in C:\TP\ASM and D:\OBJECT after searching the current directory:

\texttt{TPC MYSTUFF /OC:\TP\ASM;D:\OBJECT}

Like the \texttt{I} option, if multiple \texttt{O} options are specified, the directory lists can be concatenated.

Debug options

Turbo Pascal’s IDE features a built-in debugger; TPC has a number of command-line options that also enable you to generate debugging information for standalone debuggers, including Borland’s Turbo Debugger.

The map file option

Unlike the binary format of .EXE and .TPU files, a .MAP file is a legible text file that can be output on a printer or loaded into the editor.

The \texttt{G} option, like the \texttt{OLI Map File} command, instructs TPC to generate a .MAP file that shows the layout of the .EXE file. The \texttt{G} option must be followed by the letter \texttt{S}, \texttt{P}, or \texttt{L} to indicate the desired level of information in the .MAP file. A .MAP file is divided into three sections:

- Segment
- Publics

Chapter 9, The command-line compiler
The standalone debugging option

This is the same as the Standalone option (Options / Debugger).

Turbo Debugger (TD.EXE) is a powerful, standalone debugger that works on Turbo Pascal, Turbo C++, and Turbo Assembler .EXE files.

The /GS option outputs only the Segment section, /GP outputs the Segment and Publics section, and /GD outputs all three sections.

For modules (program and units) compiled in the {$D+,L+} state (the default), the Publics section shows all global variables, procedures, and functions, and the Line Numbers section shows line numbers for all procedures and functions in the module. In the {$D+,L-} state, only symbols defined in a unit's interface part are listed in the Publics section.

For modules compiled in the {$D-} state, there are no entries in the Line Numbers section.

When you specify the /N option on the command line, TPC appends Turbo Debugger-compatible debug information at the end of the .EXE file. Turbo Debugger includes both source- and machine-level debugging, powerful breakpoints (including breakpoints with conditionals or expressions attached to them), and it lets you debug huge applications via virtual machine debugging on a 80386 or two-machine debugging (connected via the serial port).

Even though the debug information generated by /N makes the resulting .EXE file larger, it does not affect the actual code in the .EXE file, and if it is executed from DOS, the .EXE file does not require additional memory.

The extent of debug information appended to the .EXE file depends on the setting of the $D and $L compiler directives in each of the modules (program and units) that make up the application. For modules compiled in the {$D+,L+} state, which is the default, all constant, variable, type, procedure, and function symbols become known to the debugger. In the {$D+,L-} state, only symbols defined in a unit's interface section become known to the debugger. In the {$D-} state, no line-number records are generated, so the debugger cannot display source lines when you debug the application.
The TPC.CFG file

You can set up a list of options in a configuration file called TPC.CFG, which will then be used in addition to the options entered on the command line. Each line in TPC.CFG corresponds to an extra command-line argument inserted before the actual command-line arguments. Thus, by creating a TPC.CFG file, you can change the default setting of any command-line option.

TPC allows you to enter the same command-line option several times, ignoring all but the last occurrence. This way, even though you’ve changed some settings with a TPC.CFG file, you can still override them on the command line.

When TPC starts, it looks for TPC.CFG in the current directory. If the file isn’t found there, and if you are running DOS 3.x, TPC looks in the Turbo directory (where TPC.EXE resides). To force TPC to look in a specific list of directories (in addition to the current directory), specify a /F command-line option as the first option on the command line.

If TPC.CFG contains a line that does not start with a slash (/) or a hyphen (-), that line defines a default file name to compile. In that case, starting TPC with an empty command line (or with a command line consisting of command-line options only and no file name) will cause it to compile the default file name, instead of displaying a syntax summary.

Here’s an example TPC.CFG file, defining some default directories for include, object, and unit files, and changing the default states of the $F and $S compiler directives:

```
/IC:\TP\INC;C:\TP\SRC
/OC:\TP\ASM
/UC:\TP\UNIT
/$F+
/$S-
```

Now, if you type

```
TPC MYSTUFF
```

at the system prompt, TPC acts as if you had typed in the following:

```
TPC /IC:\TP\INC;C:\TP\SRC /OC:\TP\ASM /UC:\TP\UNIT /$F+ /$S- MYSTUFF
```
Compiling in protected mode

TPCX uses the same command-line options as TPC.

If you’ve purchased the Professional package and have a 286, 386, or 486 machine with at least 1 Mb of extended memory, you can run TPCX.EXE. TPCX can build very large programs by running in protected mode and using extended memory. Note that TPCX can only make use of extended memory, not EMS.

TPCX is much larger than TPC, and running in protected mode involves more overhead than running in real mode. Use TPC to do command-line compiling unless you need the extended memory capacity of TPCX.
